The ventral horn contains many neurons that project to the thalamus. However, the properties of these spinal neurons suggest a role in proprioception, rather than in nociceptive processing (Menetrey, D. *et al.*, 1984; Ammons, W. S., 1987; Craig, A. D., Jr. *et al.*, 1989).

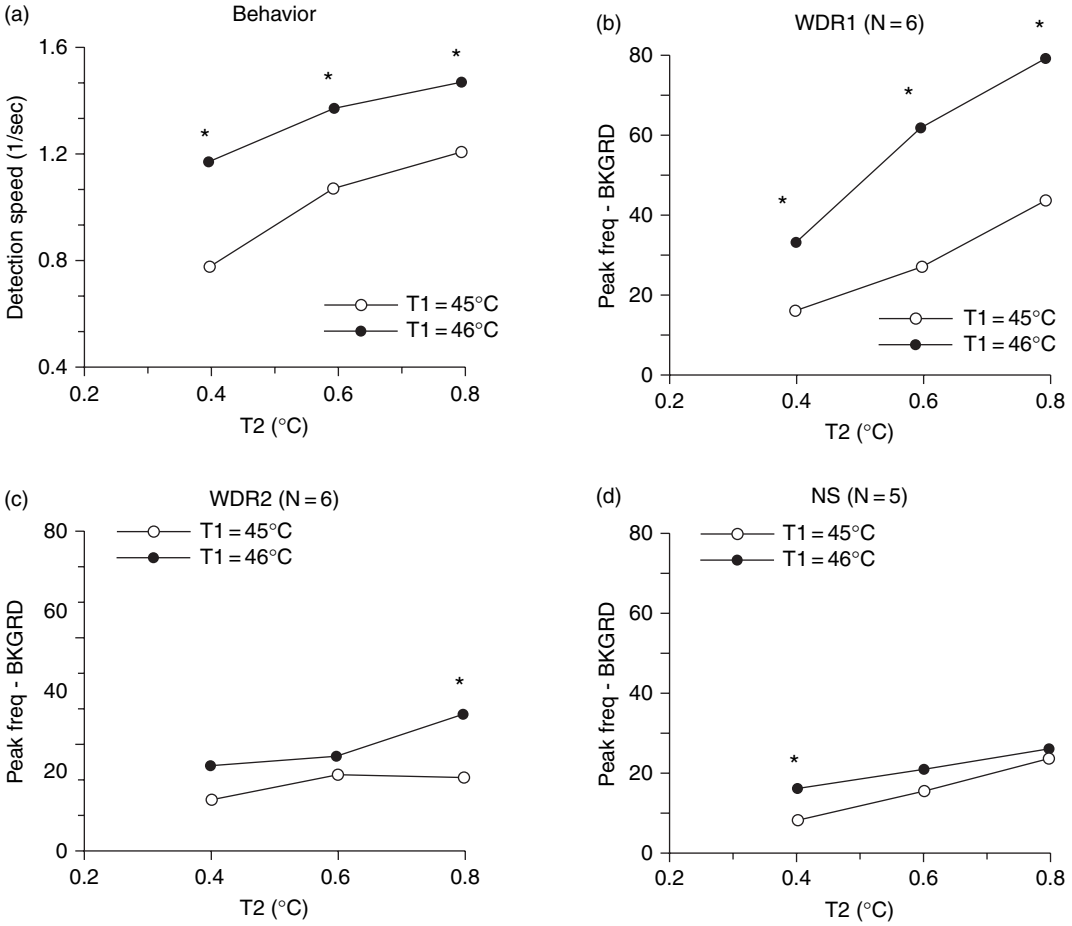

Figure 10 (a) Detection speeds in response to 0.4, 0.6, and 0.8 °C T2 stimuli from T1s of 45 and 46 °C while recording from wide-dynamic range (WDR)1, WDR2, and nociceptive-specific (NS) neurons. There was a significant increase in detection speed for each T2 temperature when Tl was 46 °C ($P < 0.01$). Each point represents the average of four trials from each of 17 neurons. (b)–(d) Responses of WDRl (b), WDR2(c), and NS (d) neurons to the same stimuli as in (a). Asterisks indicate significant increases ($P < 0.01$) in neuronal discharge when Tl was 46 °C. Each point represents the average of four trials per neuron. From Dubner, R., Kenshalo, D.R., Jr., Maixner, W., Bushnell, M. C., and Oliveras, J. L. 1989. The correlation of monkey medullary dorsal horn neuronal activity and the perceived intensity of noxious heat stimuli. J. Neurophysiol. 62, 450–457, reprinted with permission.

5.24.14 Somatotopic Organization

Submodality is encoded by neurons in different laminae. However, spatial encoding of the body surface is encoded in the medial-lateral and rostral-caudal planes (Brown, P. B. and Fuchs, J. L., 1975; Koerber, H. R. and Brown, P. B., 1977; Light, A. R. and Durkovic, R. G., 1984; Ritz, L. A. *et al.*, 1985; Brown, P. B. *et al.*, 1997; 2005). The overall map of the body surface is similar in all laminae. Figures 11 and 12 show the overall somatotopic map and more detail of the lumbar region. Overall, the map follows the segmental body plan. However, the map is distorted in the regions that encode the highly innervated digits and feet with a much greater representation of these body regions than the neck and trunk regions. The distortions in this map also represent the density of primary afferent innervation of the skin, with digits being much more densely innervated than proximal limb regions and trunk regions. These distortions are correlated to nociceptive discrimination of these same body regions with greater discrimination possible at the tips of the digits, and less on the trunk.

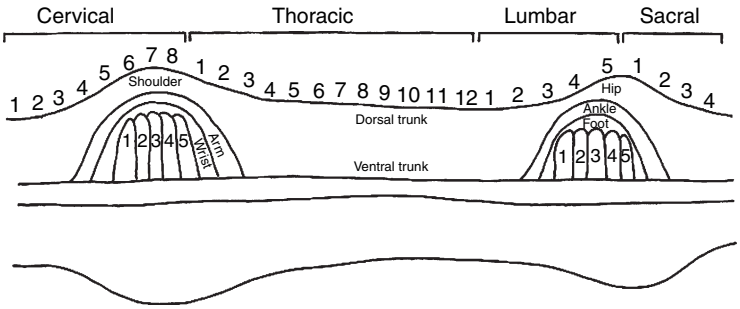

Figure 11 Somatotopic map of representation of body surface in primal spinal cord gray matter. Cervical, thoracic, lumber, and sacral segments are indicated. Maps of this sort are somewhat misleading in that receptive fields often encompass more than one of the body regions indicated on the map. For example, in the lumbar cord, receptive fields notes as hip may be restricted to the hip, but others may include a strip that includes the entire leg including the toes as well as the hip. From Light, A. R. 1992. Pain and Headache (Vol. 12): the Initial Processing of Pain and its Descending Control: Spinal and Trigeminal Systems. Karger, reprinted with permission.

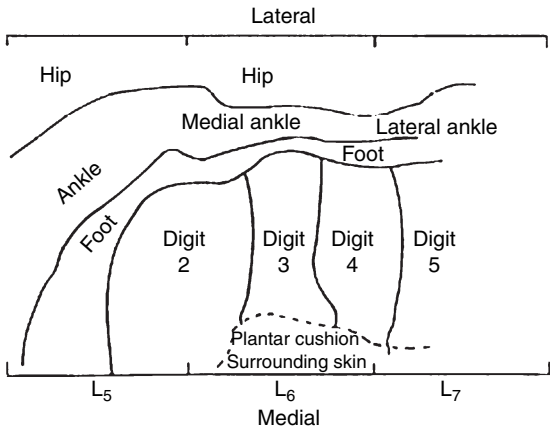

Figure 12 Somatopic organization of the foot representation in the spinal cord of cats. Most medial toe designated as toe 2; most lateral toe designated as toe 5. Map depicts density centers and does not indicate the overlapping of cell groups that have different receptive field locations. From Light, A. R. and Kavookjian, A. M. 1984. Substantia gelatinosa neurons with axons projecting to other dorsal horn laminae. Soc. Neurosci. Abstr. 10, 489, reprinted with permission.

5.24.15 Physiological Properties of Spinal Neurons

Considerable detail of the physiological properties of the intrinsic neurons of the spinal cord has been obtained by using recordings from spinal cord slices. These preparations have the advantage of a known a stable milieu surrounding the neurons. In addition, access to neurons in either the transverse or horizontal slice is less problematic because less white matter tissue must be traversed with a microelectrode before attaining recordings from the cell bodies. Because access is easier, whole-cell patch clamp of the spinal cord neurons can be readily accomplished in slice preparations. Recordings in this mode are more stable, details of synaptic inputs more easily observed, and membrane currents rather than voltage changes can be measured.

The major disadvantage, however, is that except for very recent recordings (Koerber, personal communication, 2006) the inputs to the spinal cord are removed. Thus, the adequate stimulus for the neurons is unknown in slice recordings. Since neurons are heterologous with respect to their inputs in all areas of the spinal cord, the physiological properties obtained from slice preparations can only be related to the types of inputs they receive in a broad fashion, drawing on what is know about the most common types of neurons found in the specific laminae. With these limitations in mind, still, much useful knowledge has been obtained from slice preparations. Where possible, we relate the properties observed in slice preparations to those obtained from intact preparations.

5.24.16 Intrinsic Properties of Spinal Dorsal Horn Neurons

In the spinal dorsal horn, using sharp electrode and whole-cell patch clamp recording several types of neurons have been distinguished on the basis of their intrinsic firing properties. However, these firing types and the relative numbers of each type vary depending on the experimental conditions and

species. Seven types of firing have been identified. Tonic, burst, delayed onset, gap, phasic, and single spike. These are shown in Figure 13.

Tonically firing neurons have repetitive action potentials with little frequency adaptation and little amplitude attenuation during sustained depolarization. (Figures 13 (Aa) and 13 (Ca)). The majority of tonic neurons are either WDR or nociceptive-specific neurons (Lopez-Garcia, J. A. and King, A. E., 1994). The ion channels expressed by tonic neurons that

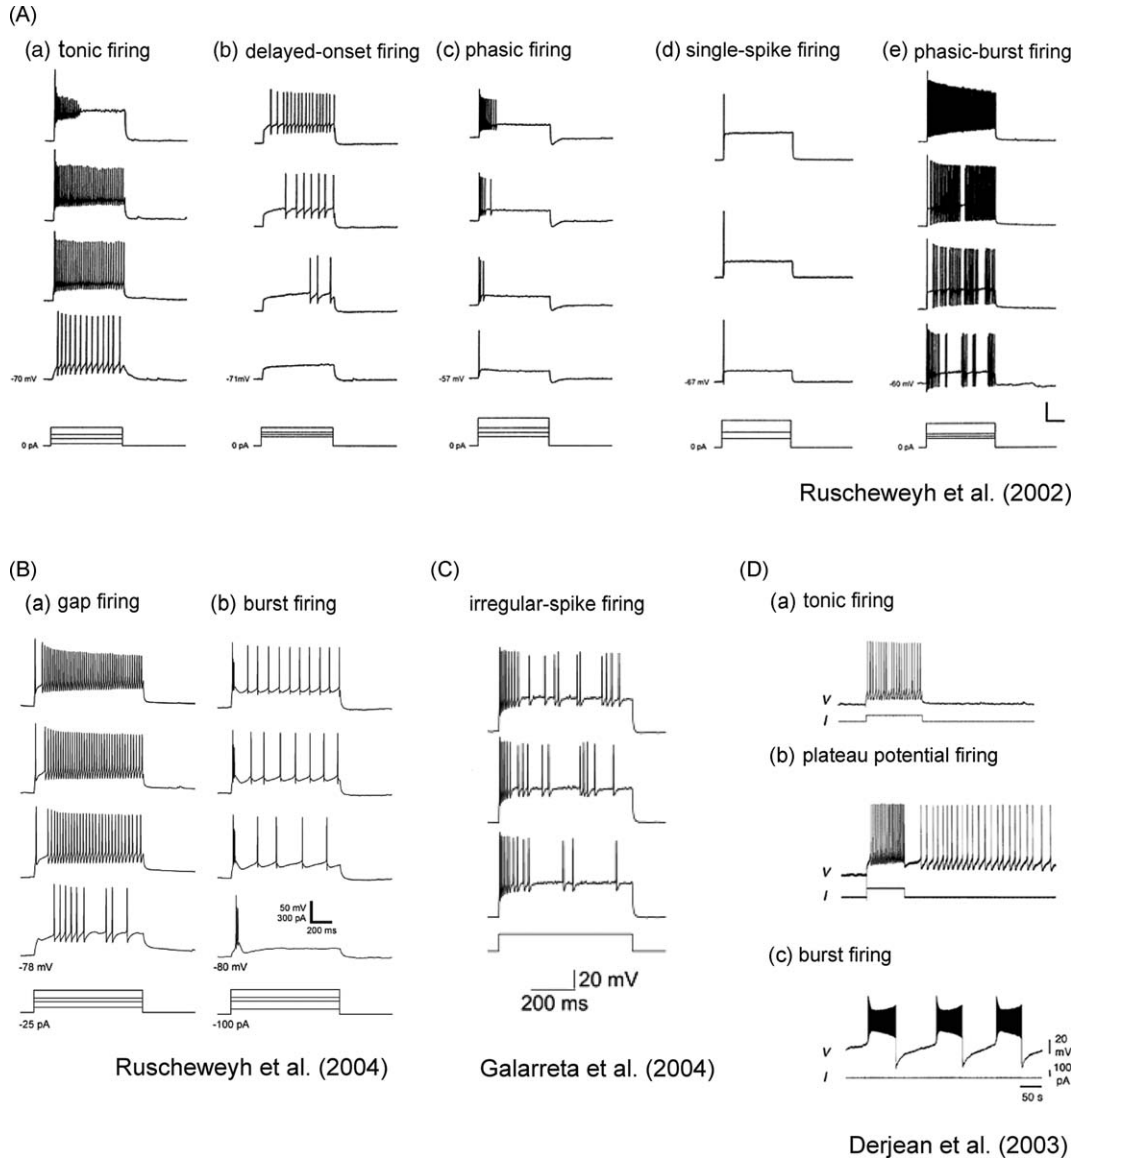

Figure 13 Firing patterns of neurons. (A) Five patterns of rat spinal dorsal horn neurons. Firing patterns were obtained in response to 1-s injections of depolarizing current (25–350 pA, 25-pA steps) at resting membrane potential. Bottom traces in (a)–(e), injected currents. (B) Typical firing patterns of lamina I projection neurons. Firing patterns were obtained in response to depolarizing current injection from hyperpolarized holding potentials. C: Deep dorsal horn neurons show three modes of firing. A: from Ruscheweyh, R. and Sandkuhler, J. 2002. Lamina-specific membrane and discharge properties of rat spinal dorsal horn neurones in vitro. Synaptic input of rat spinal lamina I projection and unidentified neurones in vitro. J. Physiol. 566(Pt 2), 355–368, reprinted with permission; C: from Derjean, D., Bertrand, S., Le Masson, G., Landry, M., Morisset, V., and Nagy, F. 2003. Dynamic balance of metabotropic inputs causes dorsal horn neurons to switch functional states. Nat. Neurosci. 6(3), 274–281, reprinted with permission.

shape this response pattern are only partly understood. It has been suggested that a voltage gated Na^+ current in combination with a pronounced delayed rectifier K^+ (K_{DR}) current and absent or weak A-type K^+ (K_A) current help to generate the basic tonic firing pattern (Ruscheweyh, R. and Sandkuhler, J., 2002; Melnick, I. V. *et al.*, 2004b). A Ca^{2+}-dependent K^+ (K_{Ca}) conductance that is sensitive to apamin regulates the discharge frequency, prolonging interspike intervals, and stabilizing firing pattern evoked by sustained membrane depolarization (Melnick, I. V. *et al.*, 2004a).

Tonic firing neurons in lamina I display prolonged excitatory postsynaptic potentials (EPSPs). The mechanisms for these prolonged EPSPs appears not to be a property of the presynaptic release, but are mediated by a persistent sodium current, $I_{Na,p}$ that amplifies and prolongs the depolarization caused by brief stimulation, combined with a persistent calcium current, $I_{Ca.p}$, that contributes to the prolongation, but not the amplification (Prescott, S. A. and De Koninck, Y., 2005). The net result is that these currents can increase integration time and encourage temporal summation of inputs, at the expense of reduced ability to encode the timing of synaptic inputs. Thus, the tonic firing neurons operate as integrators of synaptic inputs.

5.24.16.1 Burst Firing Neurons

Burst firing neurons exhibit a high-frequency barrage of action potentials that ride on the peak of a low-threshold Ca^{2+} spike (Figure 13 (Bb)). In the superficial dorsal horn (laminae I and II), the burst firing pattern was characterized by a short burst of two to four action potentials riding on a slow depolarizing wave at the onset of a depolarizing current pulse (Ruscheweyh, R. *et al.*, 2004; see Figure 13 (Bb)). With stronger current injections, this pattern could be converted to the tonic pattern (Ruscheweyh, R. and Sandkuhler, J., 2002). The burst pattern was evident only if the neuron was held more negative than −60 mV in whole-cell recordings. The current causing the bursting pattern was not affected by tetrodotoxin, but was partially blocked by Ni^{2+} and Cd^{2+}. Interestingly, the burst firing occurred almost exclusively in projection neurons and was nearly absent in nonprojection neurons, and found more often in neurons projecting to the periaqueductal gray than neurons projecting to the parabrachial region (Ruscheweyh, R. *et al.*, 2004).

The potential function of burst firing for dorsal horn nociceptive neurons is not currently understood. However, some have suggested that this pattern could contribute to the distortion of nociceptive processing in the dorsal horn that is associated with persistent pathological pain (Herrero, J. F. *et al.*, 2000). An example of an animal model of this is that increased burst firing of neurons in the spinal cord was correlated with the induction of recurrent autotomy in nerve injured rats (Asada, H. *et al.*, 1996).

5.24.16.2 Delayed-Onset Firing Neurons

Delayed-onset firing neurons demonstrate a slow ramp depolarization in response to subthreshold depolarizing current pulses (Yoshimura, M. and Jessell, T. M., 1989; Grudt, T. J. and Perl, E. R., 2002; Prescott, S. A. and De Koninck, Y., 2002; Ruscheweyh, R. and Sandkuhler, J., 2002). With higher current injections, a delay between the onset of the depolarizing current and the first action potentials gradually shortens. Repetitive firing is less regular than in tonic firing neurons, and often, the firing rate increases during the current pulse (Prescott, S. A. and De Koninck, Y., 2002; Ruscheweyh, R. and Sandkuhler, J., 2002). Yoshimura M. and Jessell T. M. (1989a) and Ruscheweyh R. and Sandkuhler J. (2002) suggested that the transient outward rectifying current (I_A) was involved in the response of neurons to sudden depolarization and served to delay the onset of the first action potentials.

Delayed-onset neurons were found almost entirely in lamina I and II, and not in deeper laminae. Whether these neurons are nociceptive, and the functional relevance of this firing pattern is not known.

5.24.16.3 Gap Firing Neurons

Gap firing neurons, also called late spiking neurons, are characterized by a considerably delayed-onset first spike flowed by tonic firing after week current pulses. With stronger current pulses, a long interval occurs between the first and second spike apparently due to a transient hyperpolarization occurring after the onset of the first depolarizing impulse (see Figure 13 (Ba)). Ruscheweyh R. *et al.* (2004) suggested that this firing pattern could be evoked only if the neuron was held at a negative potential more negative than −75 mV. They also suggested that gap firing and burst firing are the most common patterns of projection neurons with less excitable membranes having a broad action potential duel to a hump in the falling phase of the action potential. They determined that gap firing neurons preferentially project to the parabrachial region of the

brainstem, with fewer projecting to the periaqueductal gray region. Apparently, a slow I_A is required for the appearance of gap firing (Ruscheweyh, R. *et al.*, 2004).

5.24.16.4 Phasic Firing Neurons

Phasic firing neurons (Figure 13Ac) generate a short burst of action potentials during sustained depolarization. They have been reported by several groups (Thomson, A. M. *et al.*, 1989; Lopez-Garcia, J. A. and King, A. E., 1994; Prescott, S. A. and De Koninck, Y., 2002; Ruscheweyh, R. and Sandkuhler, J., 2002; Melnick, I. V. *et al.*, 2004b). The phasic pattern may be related to the density of Na^+ channels, and their voltage dependency, which may be shifted towards more positive potentials. Melnick I. V. *et al.*, (2004a) found that phasic neurons were found in the lateral part of lamina II. Lopez-Garcia J. A. and King A. E. (1994) classified most phasic neurons as nociceptive specific.

5.24.16.5 Single-Spike Firing Neurons

Single-spike firing neurons (Figure 13(Ad)) typically generate only one action potential at the onset of a current pulse, regardless of the intensity of the current pulse. A transient, voltage-dependent outward current may be involved in generating the single spike pattern. 4-aminopyridine (a K_v blocker) converts single-spike firing to tonic firing (Ruscheweyh, R. and Sandkuhler, J., 2002).

5.24.17 Relationship between Intrinsic Firing Patterns and Physiological Types of Dorsal Horn Neurons

Very few investigators have attempted to relate the firing patterns described above to the types of adequate stimuli that normally activate these neurons. Figure 14 demonstrates the data from one such attempt in rats. As this figure indicates Lopez-Garcia J. A. and King A. E. (1994) determined that the majority (81%) of WDR neurons responded with tonic firing, while nociceptive-specific neurons were mostly phasic firing neurons. Low-threshold mechanoreceptor (LTM) neurons were of both the tonic and phasic firing types. Neurons that were not fired by adequate stimuli, but demonstrated subthreshold inputs were either tonic firing or single spike type of neurons. In contrast to their conclusions, Graham B. A. *et al.* (2004) using whole-cell recordings in adult mice *in vivo* did not

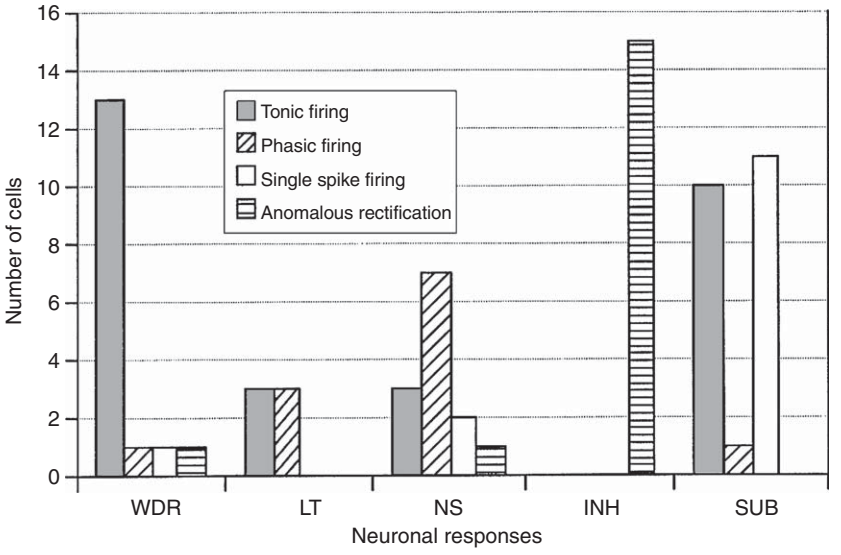

Figure 14 Distribution of electrophysiological groups from a hemisected slice preparation from rats with hindlimb attached. The number of physiologically classified wide-dynamic range neurons (WDR), low-threshold neurons (LT), nociceptive-specific neurons (NS), and neurons displaying inhibitory events (INH) are shown along with the firing type. SUB, subthreshold for firing action potentials. Adapted from Lopez-Garcia, J. A. and King, A. E. 1994. Membrane properties of physiologically classified rat dorsal horn neurons in vitro: correlation with cutaneous sensory afferent input. Eur. J. Neurosci. 6, 998–1007, with permission.

find a consistent relationship between any of the firing pattern types of neurons and physiological inputs.

Lu Y. and Perl E. R. (2003) also found that all lamina II neurons receiving inhibitory inputs from other lamina II neurons were of the phasic firing type, indicating at least some functional organization is related to the firing pattern of lamina II neurons.

Clearly, the firing patterns described here reflect specific currents mediated by specific ion channels. These specific ion channels can be altered by a number of pharmacologic agents, endogenous neurotransmitters and neuromodulators. The specificity of neurons for these channels could convey specificity of drug action on particular functional types of neurons. Some of this is the topic of Chapter 20, and much of this will be the subject of future investigations into the rich modulatory capacity of sensory neurons in the dorsal horn of the spinal cord.

5.24.18 Summary

The spinal cord dorsal horn contains the first relay for afferent inputs from the skin, muscles, and viscera of the body. The superficial dorsal horn contains at least some neurons that maintain the selectivity for modalities encoded by the primary afferent endings. These include a number of different modalities including innocuous warming, innocuous cooling, noxious mechanical, noxious thermal, noxious chemical, prurigenic (itch producing), metabolic (non-noxious signals from actively contracting muscles), and innocuous mechanical stimuli of various forms as well as other inputs from autonomic sensory neurons.

In the majority of neurons in the dorsal horn, various combinations of these inputs are integrated to allow detection of features (such as edges, speed of movement, location on the skin, noxious hot objects, etc.). Such integration allows for useful motor outputs to be generated to compensate for the inputs received, e.g., moving a limb away from a hot object, scratching a biting insect, or wiping away an insect crawling on the skin.

Many neurons in the dorsal horn also transmit selective afferent inputs, or integrated inputs to other regions of the central nervous system, including other parts of the spinal cord, the medulla, midbrain, and thalamus as well as the hypothalamus. Thus, the dorsal horn serves as the first integration and relay center for nociceptive as well as a variety of non-nociceptive inputs.

Dorsal horn neurons are modulated by inputs from higher brain centers. Inputs from other centers can greatly modify the amplitude of signals relayed from primary afferent neurons.

Dorsal horn neurons are quite heterogeneous with respect to the types of inputs that they encode, and with respect to their intrinsic membrane properties. In at least some cases, it appears that the intrinsic membrane properties are associated with the types of inputs they receive, and these intrinsic properties may allow the neurons to better integrate certain types of inputs.

Glossary

allodynia Pain caused by stimuli which would not normally cause pain (i.e., non-noxious stimuli).

angina pectoris Chest pain from cardiac ischemia.

basic somesthetic activity Description of the ongoing activity in somatosensory pathways in the absence of any deliberate stimuli.

bistable A mechanism which can essentially be in one of two states (e.g., on or off)

body image Conscious mental representation of the body.

body schema Unconscious model of the body in the brain.

bulbo-spinal control A neural control mechanism originating in the brainstem and projecting to the spinal cord.

dermatome Area of skin innervated by nerves from a given segment of the spinal cord.

diffuse noxious inhibitory controls (DNIC) Neural controls triggered by noxious stimulation of widespread areas of the body which exert an inhibitory influence on wide-dynamic-range neurons.

dorsal column stimulation Technique for inducing analgesia/hypoalgesia by electrically stimulating the dorsal columns of the spinal cord.

excitatory receptive field Area of the body (surface or interior) which when stimulated will produce excitation of a given neuron.

hyperalgesia Increased level of pain felt in response to a noxious stimulus (cf. allodynia).

hypoalgesic Pertaining to a reduction of pain.

inhibitory receptive field Area of the body (surface or interior) which when stimulated will produce inhibitory effects on the activity of a given neuron.

microelectrophoretic application Application of a substance in its ionic form from a microelectrode by the application of electrical current.

monoarthritis Inflammation of a single joint.

nociceptive stimulus Stimulus which activates nociceptive afferents (which could be a noxious stimulus (see below) or an electrical stimulus).

noxious stimulus Stimulus which causes or threatens to cause tissue damage.

polyarthritis Inflammation of several joints.

propriospinal mechanism Neural mechanism mediated entirely within the spinal cord.

radiating pain Pain which spreads from the area of stimulation to adjacent areas.

referred pain Pain which is felt in areas remote to the area of stimulation (as well as or instead of from the area of stimulation).

supraspinal mechanism Neural mechanism which at least in part, involves structures above the spinal cord.
transcutaneous electrical nerve stimulation Technique for inducing analgesia/hypoalgesia by electrically stimulating peripheral nerves through the skin (i.e., with electrodes placed on the skin).
trigeminal nucleus caudalis Most caudal part of the trigeminal sensory nuclear complex (or of the trigeminal spinal nucleus); also sometimes called the medullary dorsal horn.

5.25.1 Introduction

Wide-dynamic-range (WDR) neurons (various other names have been used by different authors for these neurones, e.g., trigger, lamina V-type, class 2, multireceptive, and convergent neurones) are found in the spinal dorsal horn (and its medullary homolog, trigeminal nucleus caudalis), both in the superficial layers and more so in deeper areas centered on lamina V. They are activated by both nociceptive and non-nociceptive stimuli and include interneurons involved in polysynaptic reflexes and neurons projecting in pathways such as the spinothalamic and spinoreticular tracts (Willis, W. D. and Coggeshall, R. E., 1991). For various reasons, these neurons are believed to play a key role in pain. For example, many procedures used to alleviate pain in man (e.g., systemic or intrathecal morphine, transcutaneous electrical nerve stimulation, and dorsal column stimulation), also result in a reduction in the responses of WDR cells to nociceptive stimuli. Indeed, some WDR neurons show patterns of activity which are more reminiscent of certain types of pain than activity in peripheral nociceptive nerves (Adriaensen, H. *et al.*, 1984; Cervero, F. *et al.*, 1988). For example, a WDR neuron may remain active after removal of a stimulus from its peripheral excitatory field (e.g., Wagman, I. H. and Price, D. D., 1969) while conversely it may remain inactive following the brief activation of inhibitory mechanisms even if there is still a stimulus on the excitatory field (Cadden, S. W., 1993). Such bistable patterns of activity might be explained by inherent properties of WDR neurons (e.g., Morisset, V. and Nagy, F., 1996) and/or their involvement in positive feedback circuits (see Cadden, S. W., 1993).

WDR neurons also constitute a site where excitatory and inhibitory influences converge. This chapter focuses on the properties of WDR neurons under physiological conditions, and most particularly, on the concept that they exhibit whole body receptive fields. One consequence of this unusual property is that it necessitates consideration of the output of the whole population of these neurons (Le Bars, D., 2002). The extent of a nociceptive focus can differ greatly depending on its cause, and consequently the global volume of information sent to the brain will also vary. Although *a priori* this volume of information is determined by the intensity, duration, and area being stimulated, it can also be altered profoundly by past and present experiences.

5.25.2 Segmental Excitatory Receptive Fields

5.25.2.1 General

WDR neurons receive information from all three groups of cutaneous afferents, that is, Aβ-, Aδ-, and C-fibers (e.g., Wagman, I. H. and Price, D. D., 1969; Menétrey, D. *et al.*, 1977). The excitatory receptive fields from which this information arises are fairly restricted in size (Figure 1). Studies in conscious monkeys illustrate that these receptive fields can expand or contract depending on the attentional state of the animal (e.g., Dubner, R. *et al.*, 1981). Although the receptive fields are usually larger than those of nociceptive-specific neurons, they can still provide useful information regarding stimulus location. Usually, these receptive fields exhibit a gradient of sensitivity: in the center even light mechanical stimuli can activate the neuron, while at the periphery only intense stimuli elicit responses (e.g., Menétrey, D. *et al.*, 1977).

When increasing intensities of mechanical or thermal stimuli are applied to the center of the receptive field, the rate and duration of neuronal firing increases (see insert in Figure 1). In this respect, these neurons seem better than nociceptive-specific neurons at encoding intensities of

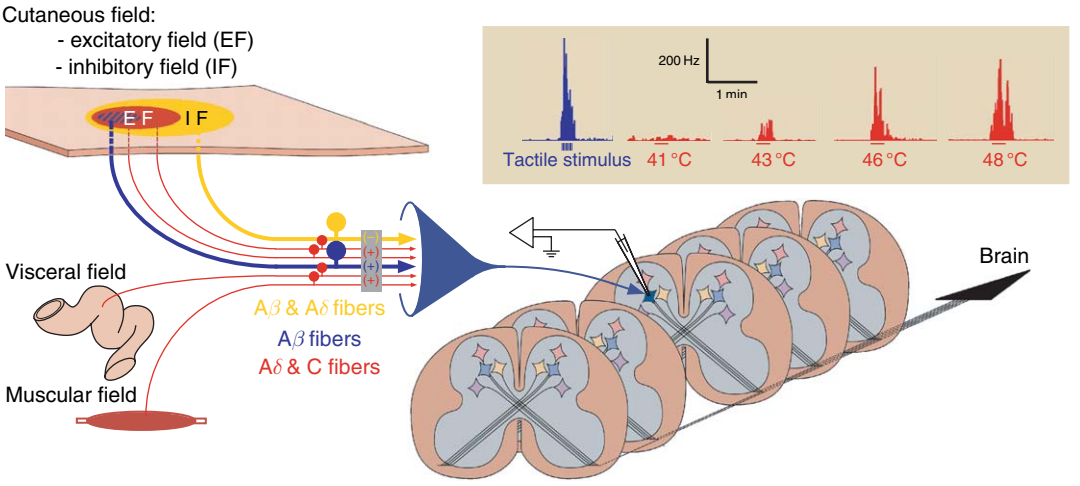

Figure 1 Schematic organization of the segmental receptive field of a wide-dynamic-range (WDR) neuron. The principal part on the skin is made up of an excitatory (EF) and an inhibitory (IF) field. The center of the EF can be activated by both innocuous and nociceptive stimuli (blue and red stripes, respectively). The periphery of the EF is activated only by nociceptive stimuli (red). The inhibitory field (yellow) is activated mainly by non-nociceptive stimuli. As shown, the receptive field may also include visceral and/or muscular components thus completing a convergence of excitatory (+) and inhibitory (−) information onto a single neuron. A ratemeter recording from a WDR neuron in the rat lumbar cord (insert, top right) shows responses to stimuli applied to the center of the excitatory field: repetitive innocuous (light pressure) stimuli produced a high level of firing while applications of radiant heat (indicated by bars with temperatures achieved) evoked responses which increased with temperature within the noxious range. Adapted from Le Bars, D. and Chitour, D. 1983. Do convergent neurons in the spinal cord discriminate nociceptive from non-nociceptive information? Pain 17, 1–19.

noxious stimuli (Hoffman, D. S. *et al.*, 1981). It is often believed that WDR neurons respond more strongly to noxious stimulation than to any form of innocuous stimulation. However, this is not quite true. In fact, the responses evoked in WDR neurons by noxious heat can be exceeded by repetitively applied innocuous mechanical stimuli (insert of Figure 1) (see Le Bars, D. and Chitour, D., 1983). Thus, firing frequency alone cannot distinguish between non-noxious and noxious stimuli. How can this fact be reconciled with WDR neurons having a central role in pain processing? It seems that the meaningful signal is the pattern of activity from the whole population of WDR cells and not simply the signals from each individual neuron. As their receptive fields overlap one another, the organization of spatial convergence from WDR neurons must be taken into account. This is illustrated by the fact that when a tactile stimulus is applied to a given territory, it activates only the few WDR neurons whose excitatory fields have centers in the territory. However, a noxious stimulus applied in the same place, will activate not only the same WDR neurons, but also those whose excitatory fields have peripheries in the territory (Figure 2).

Moreover, some WDR neurons are activated from more than one type of tissue (e.g., cutaneous and visceral or cutaneous and muscular). This convergence helps explain clinical curiosities such as radiating or referred pain, for example, to the left arm in angina pectoris. Indeed, WDR neurons can capture all the information coming from interfaces with both the external environment (the skin) and the internal milieu (viscera, muscles, etc.). This information constitutes a basic somesthetic activity. Thus, it is possible that these neurons are not involved exclusively in pain and, by transmitting this basic somesthetic activity, inform the brain that the organism is suffering no special perturbation from either external or internal sources.

5.25.2.2 Plasticity

The convergence onto a single WDR neuron is actually greater than is observed under normal conditions. This discrepancy is such that on fringes of the excitatory field, there is a zone which when stimulated will trigger a depolarization of the WDR neuron (Figure 2(c)) which normally will be insufficient to elicit action potentials. This is consistent with the observation that cutaneous receptive fields of WDR neurons are apparently smaller when mapped using natural as opposed to electrical stimulation (e.g., Mendell, L. M., 1984), given that the electrical stimuli produce more synchronized afferent activity which results in more effective

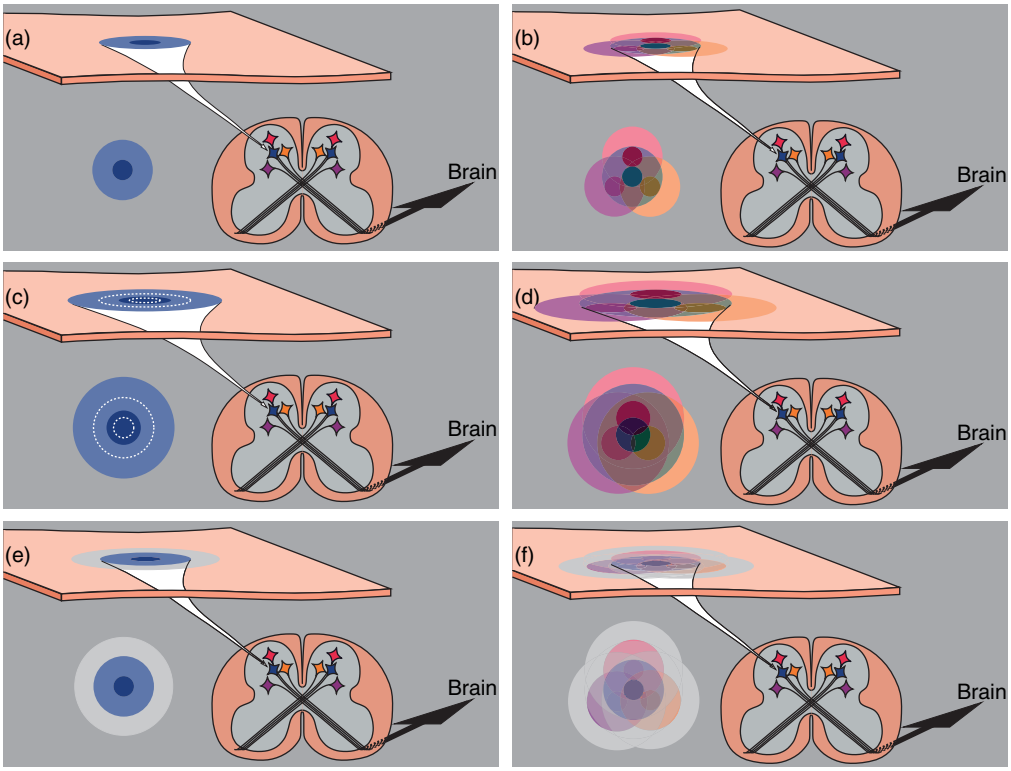

Figure 2 (a) When recordings are made from an individual wide-dynamic-range (WDR) neuron (the blue neuron in the diagram), activation by noxious stimuli applied to any part of its excitatory receptive field can be observed (blue surface on the skin). Its center (blue dark) is also sensitive to low-intensity stimuli. (b) The excitatory fields of adjacent WDR neurons overlap one another, so that a noxious stimulus will activate not only the center of some receptive fields (blue area) but also the edges of others (pale surfaces colored red, purple, and yellow). Thus, when applied to a given surface area (here the center of the blue field), a noxious stimulus will activate many neurons (four in this case) whereas a non-noxious stimulus will activate far fewer (here only one). (c) In fact the surface potentially covered by the excitatory receptive field of a WDR neuron is larger than that observed under physiological conditions. If the neuron (blue) from which recordings are being made is partially depolarized (e.g., by microelectrophoretically applying an excitatory amino acid to its membrane), an enlargement of the excitatory receptive field can be observed. This means that the span of the excitatory receptive fields is potentially much greater than shown in (a) (as indicated by the broken white lines). This is probably what occurs under inflammatory conditions. (d) Thus, considering four neurons, it can be seen that a non-noxious stimulus applied to the center of the blue field will now be able to activate the red, purple, and yellow neurons as well (cf. (b)). (e) At the periphery of their excitatory fields, WDR neurons have an inhibitory field (white zone). When mechanical stimuli are applied to this area, the neuron is inhibited. (f) The inhibitory fields of a population of adjacent WDR neurons substantially overlap one another. Thus in the center of the red field, mechanical stimuli activate the red neuron but inhibit the purple and yellow neurons. When tactile stimuli are applied to a large surface, they will not only activate the centers of excitatory fields and potentially generate a false nociceptive signal, they will also activate inhibitory fields with a resulting attenuation of the global response. This is the basis for some physical methods of pain-relief (see text).

summation of excitatory postsynaptic potentials. The concept of quiescent synapses (e.g., Wall, P. D., 1977) developed with the idea that in some conditions, this fringe of the receptive field can produce significant information transfer, that is, trigger action potentials. Such synapses can be made more efficacious experimentally by partially depolarizing a neuron using microelectrophoretic application an excitatory amino acid (Zieglgänsberger, W. and Herz, A., 1971) or pharmacologically blocking inhibitory transmitter mechanisms (e.g., Yokota, T. and Nishikawa, Y., 1979). Under these circumstances, the receptive fields enlarge and this is also seen after transient electrical stimulation of C-fibers, injury, noxious pinch, intradermal injection of capsaicin, or noxious stimulation of viscera or muscle.

Such plasticity may be triggered naturally by peripheral or central pathologies. In general, sensitization of excitatory mechanisms or a deficiency of inhibitory ones will produce both increased activity in the neuronal population associated with a painful focus and a growth of this population (Figure 2(d)). This is

illustrated by the increased size of excitatory receptive fields during acute or chronic inflammation (e.g., Grubb, B. D. *et al.*, 1993). The resulting increased information is transmitted to, and decoded in, the brain where it constitutes a form of hyperalgesia. This increase in nociceptive information varies with the volume of the body affected by the lesion (i.e., in a three-dimensional way) and also has a temporal dimension.

5.25.3 Segmental Inhibitory Receptive Field

5.25.3.1 General

WDR neurons frequently exhibit not only excitatory cutaneous receptive fields, but also inhibitory fields that are often situated proximally (e.g., Hillman, P. and Wall, P. D., 1969). When applied to this area, most mechanical stimuli, notably those of low intensity, inhibit the activity of WDR neurons. It is often implied that these phenomena are triggered only by the activation of Aβ-fibers. However, numerous studies have demonstrated that activation of Aδ-fibers results in more powerful inhibitions (e.g., Chung, J. M. *et al.*, 1984). Thus the activation of a pool of Aδ-fiber terminals will both activate those WDR neurons with excitatory receptive fields in this particular area and inhibit those with overlapping inhibitory receptive fields. As described below, the final output from these neurons constitutes a contrasted picture reminiscent of the lateral inhibition described in other systems (e.g., visual and touch).

5.25.3.2 Plasticity

It is important to consider the overlap of excitatory and inhibitory fields of neighboring WDR neurons (Figures 2(e) and 2(f)). The organization of the inhibitory fields offers an explanation for how, at least in nonpathological conditions, the high levels of activity produced in individual neurons by application of multiple non-nociceptive stimuli to large surface areas (incorporating numerous centers of excitatory fields) do not constitute a nociceptive signal. Such an eventuality is prevented by the concomitant stimulation of numerous inhibitory fields which attenuates the overall response of the neuronal population. in contrast, a deficit of such inhibitory effects will result in a greater amount of activity being produced by harmless stimuli. Once transmitted to and decoded by the brain, such information could constitute a form of allodynia such as that triggered by brushing the skin with cotton wool, which is characteristic of some neuropathies.

The convergence of excitatory and inhibitory influences may also explain the hypoalgesic effects of stimulating parts of the body close to a painful focus, for example, by rubbing or transcutaneous electrical nerve stimulation (TENS). Indeed, the fact that large and fine cutaneous afferent fibers interact with this potential effect has been known for a long time (e.g., Head, H. *et al.*, 1905; Noordenbos, W., 1959; Melzack, R. and Wall, P. D., 1965).

5.25.4 Perturbance of the Basic Somesthetic Activity by a Painful Focus

In addition to the segmental inhibitory influences discussed above, WDR neurons are inhibited by nociceptive stimulation of areas of the body remote from their segmental receptive fields. These effects involve propriospinal and supraspinal mechanisms. The former can be observed in the dorsal horn of spinal animals (e.g., Gerhart, K. D. *et al.*, 1981) but the underlying mechanisms have not been investigated in detail. The supraspinal mechanisms are observed in intact but not in spinalized animals and have been studied more extensively (see Chapter Diffuse Noxious Inhibitory Controls (DNIC)).

In fact, any noxious stimulus will activate descending bulbo-spinal controls and these will strongly depress the activity of neurons in the spinal dorsal horn and its trigeminal homolog. In several species, the vast majority of WDR neurons (and some nociceptive-specific neurons) are profoundly inhibited by noxious stimulation of any part of the body provided it is not the neuron's own excitatory receptive field. In effect, the receptive fields of these neurons are made up by the whole body – mainly in the form of an inhibitory receptive field except in its own neural segment where both inhibitory and excitatory fields exist. These whole body phenomena which have been termed diffuse noxious inhibitory controls (DNIC) work by hyperpolarizing WDR neurons (see Chapter Diffuse Noxious Inhibitory Controls (DNIC)).

In summary, a noxious focus activates a segmental subset of WDR neurons and inhibits all other WDR neurons (Figure 3(b)). This mechanism effectively improves the signal-to-noise ratio by increasing the contrast between the activities of the excited neurons and the depressed activity of the remainder.

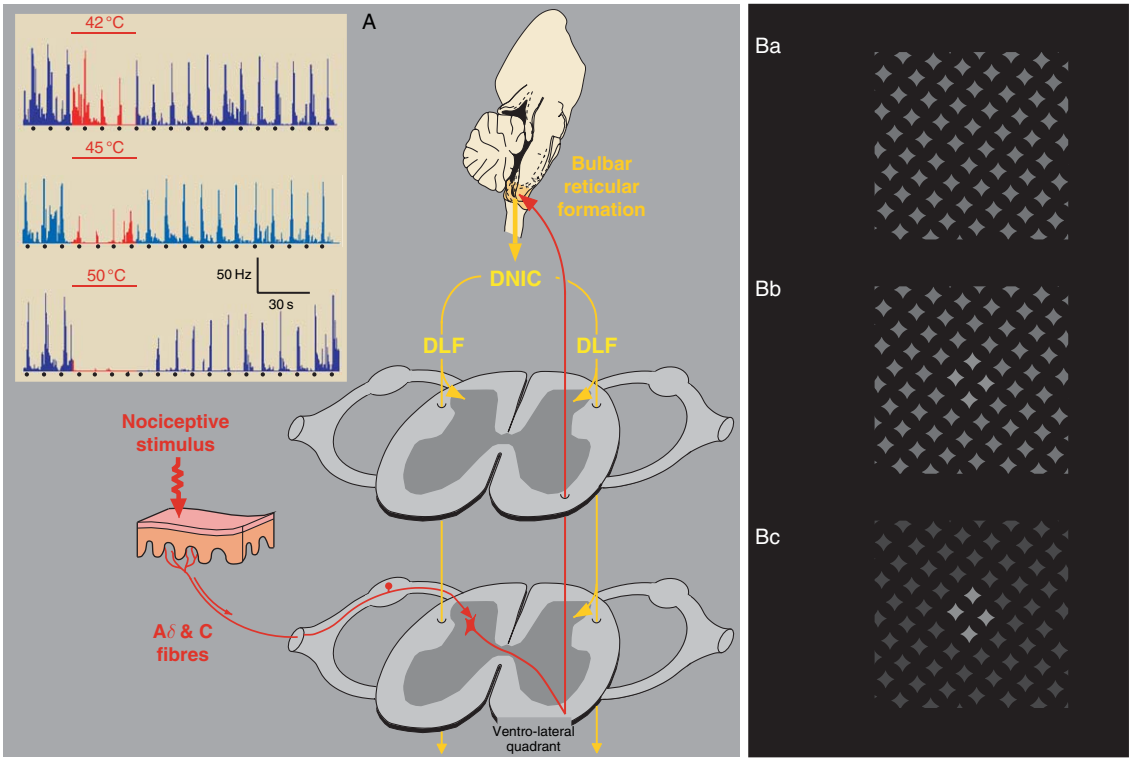

Figure 3 (A) Triggering of descending inhibitory controls by nociceptive stimuli. One consequence of a painful focus is the modification of activity of a whole population of WDR neurons. Nociceptive signals pass up the ventrolateral quadrant to activate structures in the bulbar reticular formation. These structures in turn send signals down the dorsolateral cord to trigger powerful inhibitory mechanisms in all segments not concerned with the initial stimulus. The insert (top left) shows a recording from a WDR neuron in the rat lumbar cord whose receptive field on the extremity of a hindpaw, was mechanically stimulated by a paint brush once every 10 s (indicated by black spots). The resulting activity was inhibited by the application of remote noxious stimuli (immersion of the tail in 42, 45, or 50 °C water). This inhibition increased with the water temperature. (B) Schematization of the activity of all WDR neurons: (Ba) in the absence of a painful focus, these neurons produce the basic somaesthetic information, consisting of signals from the body about its immediate environment; (Bb) as a consequence of a painful focus, some of these neurons are activated (four of them in the center of this diagram), but it is difficult to extract this information because of the background noise; (Bc) however the inhibition of the other neurons by the mechanisms described in (a), makes it possible for the brain to extract the information about the painful focus due to the contrast between the activated and the inhibited neurons. DLF, dorsolateral funiculus; DNFC, diffuse noxious inhibitory control.

Interestingly, DNIC are exacerbated in experimental models of clinical pain (e.g., monoarthritis, polyarthritis, and peripheral mononeuropathies; e.g., Danziger, N. *et al.*, 2000).

5.25.5 Multiple or Vast Painful Foci

If it is accepted that WDR neurons are important in pain, then interactions between nociceptive signals from separate parts of the body must result in interactions between the corresponding pains. In fact, a painful stimulus can decrease or even mask pain arising from another part of the body (see Chapter Diffuse Noxious Inhibitory Controls (DNIC)).

The size of a painful focus can vary greatly depending on the underlying pathology and consequently the volume of nociceptive information sent to the brain will also vary. How do WDR neurons behave when noxious stimuli are applied to increasingly large surface areas? In fact, two opposite effects are observed: up to a particular area of stimulation – approximately twice that of the neuron's excitatory field – there is an accelerating transfer function; however for larger surface areas, the responses gradually diminish (Bouhassira, D. *et al.*, 1995). This is consistent with findings in humans that noxious thermal stimulation of increasingly large areas of skin causes an increasingly painful sensation only over a restricted range of surface areas (e.g., Hardy, J. D.

et al., 1952) and that painful thermal stimuli evoke pleasant warmth when applied to larger areas (Melzack, R. *et al.*, 1962). The classical poor correlation between the extent of an injury and the intensity of pain may also involve such mechanisms.

Thus it seems that a painful focus activates a negative feedback loop affecting WDR neurons only when it generates a sufficient volume of nociceptive information. This volume is undoubtedly determined by the intensity of the stimulus, the area to which it is applied, and its duration. In this respect, the role of temporal summation in triggering inhibitory bulbo-spinal mechanisms must be addressed (Gozariu, M. *et al.*, 1997).

5.25.6 Summary and Conclusions

The global population of WDR neurons is activated continuously but unpredictably by all the non-noxious stimuli provided by the environment. The resulting basic somaesthetic activity can constitute either noise from which the brain may have difficulty extracting a clear signal, or a significant message. According to modern neuropsychological concepts, this on-going information from the whole body, along with that from other sensory systems, notably the vestibular and visual systems, is integrated to generate a permanent, unconscious, representation of the physiological reality of self. At the beginning of the twentieth century, the great neurologist Henry Head proposed that our brains contain two schemas – "a postural model of ourselves and another schema allowing the recognition of the locality of the stimulated spot" (Head, H. and Holmes, G., 1911). However, following Schilder P. (1950), the simple term body schema is usually used to refer to both models. Even though the terms are sometimes used interchangeably, it is advisable to distinguish body schema which is an unconscious cerebral model of the body, from body image which is a conscious mental representation. WDR neurons are good candidates for constructing and endlessly rebuilding the memory of one's physical self (Le Bars, D., 2002). Previous experiences, be they neutral, pleasant, or unpleasant (e.g., pain), contribute to the building of this memory; all will have activated WDR neurons. Intense or long-lasting pains are probably among the physical causes which most commonly disturb the body schema: they generate a painful body by focusing attention on one part of the body to the detriment of the others. The body schema then emerges from relative unconsciousness and the painful focus becomes pre-eminent and relatively oversized. Spino-bulbo-spinal mechanisms could underlie this over-representation by providing a filter which imposes the nociceptive signal to the detriment of information from the rest of the body.

After all, this is what happens within any large gathering: silence is necessary if a speaker is to be heard. DNIC establish such silence among spinal neurons. Conversely, a hubbub does not reduce the speaker to silence, but drowns his speech to the extent that he cannot be heard. This is one way in which morphine works – and DNIC are extremely sensitive to low doses of morphine (see Le Bars, D. *et al.*, 1995).

In summary, WDR neurons do not constitute a single-channel transmission network. Nociceptive information is processed by complex mechanisms which can modify the gain of the system. The modulation of this gain is determined by the three-dimensional characteristics of the painful focus – not only its intensity and duration but also its surface area. Beyond a critical level, an increase in the number of activated noci-responsive neurons is associated with a decrease in their individual responses.

A complete analysis of nociceptive processes must consider not only a large population of neurons but also their interactions. Pain in clinical practice is not punctuate and involves a large number of excitatory receptive fields of peripheral fibers and central neurons. When several foci coexist, the global signal from WDR neurons may be polymorphic with the resulting pain showing fluctuations, instability, or even versatility due to the resulting interactions.

Glossary

adaptor protein A protein which is accessory to main proteins in a signal transduction pathway. These proteins often lack any intrinsic enzymatic activity themselves, but instead mediate specific protein-protein interactions that drive the formation of protein complexes.

allodynia Pain due to a stimulus that does not normally provoke pain.

antisense oligonucleotides Single strands of DNA or RNA that are complementary to a chosen sequence. Antisense RNAs prevent translation of complementary RNA strands by binding to them.

apoptosis An orchestrated series of biochemical events leading to cell death.

carrageenan A linear sulphated polysaccharide extracted from red seaweeds that is used as an inflammatory agent.

central sensitization Activity- or injury-dependent changes in the excitability of central nervous system (CNS) neurons, typically in pain pathways, and is reflected by increased spontaneous activity, reduced thresholds or increased responsiveness to afferent inputs, prolonged after- discharges to repeated stimulation, and the expansion of the peripheral receptive fields of central neurons.

complete Freund's adjuvant An antigen solution composed of inactivated and dried *Mycobacterium tuberculosis* emulsified in mineral oil, used as an immunopotentiator (booster of the immune system) and inflammatory agent.

2-deoxy-D-glucose A marker for tissue glucose use.

excitatory amino acids Amino acid neurotransmitters that include aspartate and glutamate. Glutamate is the most abundant fast excitatory neurotransmitter in the mammalian nervous system.

excitatory postsynaptic potential (EPSP) Is a temporary increase in postsynaptic membrane potential caused by the flow of positively charged ions into the postsynaptic cell.

glial cells Commonly called neuroglia or simply glia, are non-neuronal cells that provide support and nutrition, maintain homeostasis, form myelin, and participate in signal transmission in the nervous system.

homosynaptic sensitization Facilitation of activity occuring at the synapses that connect two neurons.

hyperalgesia An increased response to a stimulus which is normally painful. Primary hyperalgesia occurs at the site of injury, and secondary hyperalgesia in adjacent, or sometimes remote, uninjured tissue.

inhibitory postsynaptic potential (IPSP) Is the change in membrane voltage of a postsynaptic neuron which results from synaptic activation of inhibitory neurotransmitter receptors.

ion channels Pore-forming proteins that help to establish and control the small voltage gradient across the plasma membrane of all living cells by allowing the flow of ions down their electrochemical gradient.

long-term potentiation (LTP) An increase in the strength of a chemical synapse that lasts from minutes to several days.

neuropeptides A variety of peptides found in neural tissue.

neurotrophins Also called ''neurotrophic factors'', are a family of protein which induce the survival of neurons. They belong to a family of growth factors, secreted proteins which are capable of signaling particular cells to survive, or differentiate, or grow.

phenotype switch A process by which neurons change their phenotype and begin to produce and release substances they normally do not produce.

protein kinase Is a kinase enzyme that modifies other proteins by chemically adding phosphate groups to them (phosphorylation).

protein tyrosine phophatase (PTP) An enzyme that remove phosphate groups from phosphorylated tyrosine residues on proteins.

scaffold proteins Proteins that bring together various other proteins in a signaling pathway and allows for their interaction. They recruit downstream effectors in a pathway and enhance specificity of the signal.

secondary messengers Secondary messengers are a component of signal transduction cascades that utilize receptors on the surface of the plasma membrane which are generally coupled to a kinase on the interior surface of the membrane. The kinase then phosphorylates another molecule which carries out another action.

transcription factor A protein that works in concert with other proteins to either increase or decrease the transcription of genes.

transporters Membrane-bound pumps that move biochemicals and other atomic or molecular substances across membranes.

wide dynamic range A property of spinal cord dorsal horn neurons (typically in lamina V) that exhibit graded responses to non-noxious and noxious stimuli since they receive convergent input from non-nociceptive and nociceptive primary afferent fibers.

wind-up Cumulative depolarization, action potential bursting and afterdischarges in spinal cord dorsal horn neurons following high frequency, C-fiber strength electrical stimulation or intensely noxious natural stimuli.

5.26.1 Characteristics of Hyperalgesia

5.26.1.1 Definition and Historical Background

The term hyperalgesia was first coined by Gowers in the 1800s, and is often still used as a term to define what Hardy J. D. (1956) described as "a state of increased pain sensation induced by either noxious or ordinarily nonnoxious stimulation of peripheral tissue." The International Association for the Study of Pain (IASP) currently uses separate terms for the two reactions Hardy described. Thus, hyperalgesia is defined as "an increased response to a stimulus which is normally painful," while "pain due to a stimulus that does not normally provoke pain" is known as allodynia (IASP website). Over the years, hyperalgesia (not distinguished from allodynia) has been further separated into primary and secondary hyperalgesia; primary hyperalgesia occurs at the site of injury, and secondary hyperalgesia in adjacent, or sometimes remote, uninjured tissue. Primary hyperalgesia is reflected by a hypersensitivity to thermal and mechanical stimuli, and is driven largely by sensitization of peripheral nociceptors. Secondary hyperalgesia is predominantly characterized by hypersensitivity to mechanical stimuli, and likely involves central sensitization. Central sensitization refers to activity- or injury-dependent changes in the excitability of central nervous system (CNS) neurons, typically in pain pathways, and is reflected by increased spontaneous activity, reduced thresholds or increased responsiveness to afferent inputs, prolonged after-discharges to repeated stimulation, and the expansion of the peripheral receptive fields of central neurons (Woolf, C. J. *et al.*, 1988; Coderre, T. J. *et al.*, 1993). Although central sensitization has been demonstrated in neurons throughout the somatosensory nervous system, the mechanisms underlying central sensitization have been largely generated from studies concentrating on spinal cord dorsal horn neurons. The characteristics and underlying mechanisms of central sensitization in spinal cord dorsal horn neurons will be the main focus of the remaining sections of this chapter, and will be a recurring theme in various chapters of this volume that address alterations in pain processing associated with injury or disease of peripheral tissue, primary afferent nerves, or CNS structures.

5.26.1.2 Precipitating Conditions for Hyperalgesia and Evidence of Central Sensitization

5.26.1.2.1 Cutaneous injury

5.26.1.2.1.(i) Heat injury Considerable evidence demonstrates that heat injury of the skin produces a sensitization of peripheral nociceptors. Peripheral sensitization occurs both in Aδ and C-fiber nociceptors (Beitel, R. E. and Dubner, R., 1976; Fitzgerald, M. and Lynn, B., 1977), and largely accounts for primary hyperalgesia (Meyer, R. A. and Campbell, J. N., 1981; Torebjörk, H. E. *et al.*, 1984). In addition, dorsal horn neurons fire with increasing frequency in response to repeated applications of a noxious heat stimulus (Perl, E. R. *et al.*, 1976, Kenshalo, D. R. *et al.*, 1979) or following thermal injury (Price, D. D. *et al.*, 1978; Kenshalo, D. R. *et al.*, 1982), indicative of central sensitization. In addition to the sensitization and prolonged excitation of dorsal horn cells, noxious stimulation associated with tissue injury also produces an expansion of the receptive fields of dorsal horn neurons. Thus, neurons in the dorsal horn of the spinal cord with receptive fields adjacent to a cutaneous heat injury expand their receptive fields to incorporate the site of injury (McMahon, S. B. and Wall, P. D., 1984).

Evidence that central sensitization contributes to secondary hyperalgesia after heat injury was supported initially by reports that heat injury-induced cutaneous hyperalgesia spreads well beyond the area of nociceptor sensitization. Thalhammer J. G. and Lamotte R. H. (1982) found that a heat injury in one half of a cutaneous nociceptor's receptive field did not produce heat sensitization in the other half, despite the fact that hyperalgesia spread into this area. Typically, nociceptor sensitization associated with injury is restricted to about 5–10 mm of the site of injury (Fitzgerald, M., 1979) while, in contrast, cutaneous hyperalgesia spreads as far as 10–20 cm beyond the site of injury (Hardy, J. D. *et al.*, 1950).

Although it is commonly reported that there is mechanical, but not heat hyperalgesia in the secondary zone (Raja, S. N. *et al.*, 1984), secondary heat hyperalgesia has been reported in some cases (Pedersen, J. L. and Kehlet, H. 1998). Importantly, secondary heat hyperalgesia is significantly reduced when lidocaine is administered i.v. prior to heat injury (Holthusen, H. *et al.*, 2000), suggesting that central sensitization plays a role in its initiation. Animal behavioral studies support this conclusion, as the spread of hyperalgesia to the rat hind paw

contralateral to the paw that received a thermal injury is unaffected by either deafferentation or anesthetic blocks of the injured hind paw following the injury, but is prevented if deafferentation or anesthetic block precedes the injury (Coderre, T. J. and Melzack, R., 1985; 1987).

5.26.1.2.1.(ii) Mechanical injury Mechanical injury of the skin also produces both primary and secondary hyperalgesia, as has been demonstrated in the rat plantar incision model (Brennan, T. J. *et al.*, 1996), as well as following incision of human skin (Kawamata, M. *et al.*, 2002a). Although both pre- and postincisional administration of intrathecal (i.t.) morphine or bupivacaine reduce secondary hyperalgesia in the rat model (Zahn, P. K. and Brennan, T. J., 1999), only preincisional administration of s.c. or i.v. lidocaine reduce secondary hyperalgesia in humans (Kawamata, M. *et al.*, 2002a). These results again support a role for central sensitization in the initiation of secondary hyperalgesia after mechanical skin injury. This conclusion is also consistent with the finding that rat plantar incisions or other mechanical injuries produce an increase in the responsiveness of spinal wide dynamic range (WDR) neurons to innocuous and noxious stimuli, as well as increases in their receptive fields (Cervero, F. *et al.*, 1988; Kawamata, M. *et al.*, 2002b).

5.26.1.2.1.(iii) Capsaicin Capsaicin, the active ingredient of hot chilli peppers, produces hyperalgesia in both animals (Gilchrist, H. D. *et al.*, 1996) and humans (Carpenter, S. E. and Lynn, B., 1981) when injected or applied to the skin. Evidence that capsaicin-induced hyperalgesia depends on central sensitization initially came from animal studies that showed that intradermal injections of capsaicin produced enhanced excitability of spinal cord dorsal horn neurons in cats (Simone, D. A. *et al.*, 1989) and monkeys (Dougherty, P. M. and Willis, W. D., 1992). In both monkeys (Baumann, T. K. *et al.*, 1991) and humans (Lamotte, R. H. *et al.*, 1992), capsaicin injections produce extensive, spreading hyperalgesia without producing the same degree of spreading sensitization of primary afferent nociceptors. Indeed, capsaicin caused the spread of both brush allodynia and pinprick hyperalgesia beyond the borders of the territory of the nerve which innervates the injected skin area (Sang, C. N. *et al.*, 1996), suggesting that there is extraterritorial pain that is dependent on central sensitization. Furthermore, in humans, hyperalgesia to punctate mechanical stimuli, which develops after intradermal injection of capsaicin, is maintained even after anesthetizing the region where capsaicin was injected (Lamotte, R. H. *et al.*, 1991). However, if the skin region is anesthetized prior to capsaicin injection, cutaneous hyperalgesia does not develop. Furthermore, hyperalgesic responses to capsaicin can be prevented if the area of skin where the injection is made is rendered anesthetic by a proximal anesthetic block of the peripheral nerve which innervates it. Thus, for hyperalgesia to develop it is critical that initial inputs from the injury reach the CNS. However, once hyperalgesia is established, it does not need to be maintained by inputs from the injured peripheral tissue. In support of this, Torebjörk H. E. *et al.* (1992) have shown that pain thresholds to intraneural electrical stimulation of afferent fibers are dramatically reduced following intradermal capsaicin injection in the skin from which the stimulated nerve emanates: neural stimulation which was felt as tactile before administration of capsaicin, was painful after capsaicin. Importantly, this reduced pain threshold is evident even when the sensory projected field of the afferent nerve is anesthetized after the capsaicin injection. Again, a state of central sensitization is indicated since once they have established their effects, inputs from the injured region are not required to maintain the lowered threshold.

5.26.1.2.2 Peripheral nerve stimulation

Much of the early evidence that spinal mechanisms contribute to hyperalgesia and allodynia came from studies that used peripheral nerve stimulation as a conditioning stimulus, and assessed the influence of the conditioning on spinal function or the function of spinal output neurons. Early studies showed that repeated high-frequency C-fiber afferent stimulation sequentially increases dorsal horn activity resulting in a prolonged discharge of the cell, lasting from seconds to minutes poststimulation (Mendell, L. M. and Wall, P. D., 1965; Mendell, L. M., 1966). This phenomenon, which has been labeled as windup, results from a homosynaptic sensitization (Woolf, C. J. *et al.*, 1988) of dorsal horn neurons, and likely represents a short-term sensitization of dorsal horn neurons that underlies the intense reactions and lingering after sensations to stimuli at the pain tolerance level. Although windup is not synonymous with central sensitization (Woolf, C. J., 1996), stimulation that causes windup can produce some of the classical characteristics of central sensitization including expansion of dorsal horn neuronal receptive fields and enhanced spinal neuronal

responses to C-fiber, but not A-fiber electrical stimulation (Li, J. *et al.*, 1999).

In early studies of central mechanisms of hyperalgesia, it was shown that noxious electrical stimulation of cutaneous and muscle afferent nerves (Woolf, C. J., 1983; Wall, P. D. and Woolf, C. J., 1984), as well as cutaneous (Woolf, C. J., 1983) and deep (Woolf, C. J. and McMahon, S. B., 1985) tissue injury, produce an increase in the excitability of the ipsilateral and contralateral flexor efferent nerves in response to noxious mechanical stimulation of the hind paw. Because the increased excitability in the contralateral flexor efferent nerve is maintained even after inputs from the injured paw are blocked by local anesthesia, the results suggest that central, not peripheral, changes underlie this effect.

Although typically associated with hippocampal neurons, evidence suggests that the phenomenon long-term potentiation (LTP) can also be elicited in spinal cord dorsal horn neurons after stimulation of primary afferents in transverse spinal cord slices (Randic, M. *et al.*, 1993; Lozier, A. P. and Kendig, J. J., 1995), as well as *in vivo* after electrical nerve stimulation (Svendsen, F. *et al.*, 1997; 1999) or intense natural noxious stimulation (Rygh, L. J. *et al.*, 1999). Importantly, LTP induced by electrical nerve stimulation or noxious stimulation is maintained after lidocaine block distal to the stimulation site in the sciatic nerve (Svendsen, F. *et al.*, 1999) or proximal to the site of noxious stimulation (Rygh, L. J. *et al.*, 1999).

5.26.1.2.3 Inflammation

5.26.1.2.3.(i) Subcutaneous inflammation Subcutaneous injections of inflammatory substances such as carrageenan and complete Freund's adjuvant (CFA) in the rat hind paw produce thermal hyperalgesia and mechanical allodynia (Buritova, J. *et al.*, 1996; Arevalo, M. I. *et al.*, 2003), as well as a sensitization of peripheral nociceptors (Kocher, L. *et al.*, 1987; Andrew, D. and Greenspan, J. D., 1999). There is also evidence of central sensitization associated with peripheral inflammation. Subcutaneous carrageenan injections produce increased excitability of rat spinal cord neurons as shown by increased responses to mechanical and electrical stimulation, enhanced windup, expanded receptive fields (Hedo, G. *et al.*, 1999; Torsney, C. and Fitzgerald, M., 2002), and increased flexor efferent neuron responsiveness (Xu, X.-J. *et al.*, 1995). Subcutaneous injections of CFA in rats also produce central sensitization, as evidenced by the enhancement of dorsal horn neurons spontaneous activity and increased responsiveness to thermal, mechanical and electrical nerve stimulation (Hylden, J. L. K. *et al.*, 1989; Ren, K. *et al.*, 1992). After subcutaneous CFA, there is also an increased ability to induce LTP (Vikman, K. S. *et al.*, 2003), expanded receptive fields in rat dorsal horn neurons (Hylden, J. L. K. *et al.*, 1989; Ren, K. *et al.*, 1992), and an increase in the excitability of flexor efferent neurons (Seybold, V. S. *et al.*, 2003).

5.26.1.2.3.(ii) Joint inflammation Injection of kaolin and carrageenan into the rat knee joint produces limping and guarding of the limb (Sluka, K. A. and Westlund, K. N., 1993), as well as a sensitization of peripheral nociceptors (Neugebauer, V. and Schaible, H. G., 1988). The same stimulus produces enhanced responsiveness of spinal cord dorsal horn neurons to normal movement or tactile stimulation of the knee joint (Neugebauer, V. and Schaible, H. G., 1988; 1990), as well as an expansion of the receptive field of dorsal horn neurons that respond to joint input (Neugebauer, V. and Schaible, H. G., 1990). There is also an expansion of dorsal horn neuron receptive fields following the induction of polyarthritis in multiple joints three weeks or more following CFA injections to the rat tail (Menétrey, D. and Besson, J. M. 1982; Calvino, B. *et al.*, 1987).

5.26.1.2.4 Peripheral nerve injury

Traumatic (Bennett, G. J. and Xie, Y. K., 1988; Seltzer, Z. *et al.*, 1990; Kim, S. H. and Chung, J. M., 1992; Decosterd, I. and Woolf, C. J., 2000), inflammatory (Eliav, E. *et al.*, 1999; Milligan, E. D. *et al.*, 2003), or chemical (Tanner, K. D. *et al.*, 1998; Polomano, R. C. *et al.*, 2000) injury of peripheral nerves induces heat and/or mechanical hyperalgesia, or mechanical and/or cold allodynia in animal models. While there is an established contribution of peripheral pathology to hyperalgesia and allodynia in these models (Chen, Y. and Devor, M., 1998; Liu, X. *et al.*, 1999), it is also clear that central sensitization plays a critical role. Thus, 9–11 days after chronic constriction injury (CCI) of the rat sciatic nerve, lumbar spinal cord dorsal horn neurons exhibit abnormal characteristics including spontaneous activity, exaggerated, and prolonged responses to noxious and innocuous mechanical stimulation (Laird, J. M. and Bennett, G. J., 1993), with prolonged after-discharges more prevalent in WDR neurons, as opposed to nociceptive-specific neurons (Sotgiu, M. L. *et al.*, 1995; Pitcher, G. M. and Henry, J. L., 2000). Two weeks after L5/L6 spinal nerve ligation (SNL), rat dorsal horn neurons also show increased spontaneous firing with irregular firing patterns (Suzuki, R. and Dickenson, A. H., 2005).

Thresholds for excitatory postsynaptic potentials (EPSPs) of lamina II neurons are dramatically lower after CCI, and spared nerve injury (Kohno, T. *et al.*, 2003), and there is a long-lasting posttetanic potentiation of sciatic-evoked A-fiber superficial dorsal horn field potentials that is present over the same time course as thermal hyperalgesia in CCI rats (Draganic, P. *et al.*, 2001). Tight ligation of the L5/L6 spinal nerve also results in a lower threshold for activation of C-fiber-driven dorsal horn field potentials, and for the induction of LTP in dorsal horn neurons (Xing, G. *et al.*, 2003).

Increases in spontaneous and evoked activity in dorsal horn neurons of CCI rats are paralleled by increases in [^{14}C]-2-deoxyglucose metabolic activity throughout the lumbar spinal dorsal horn, with greater increases in the medial portion of the ipsilateral dorsal horn (Mao, J. *et al.*, 1992a). Fos protein expression, often used as a measure of neuronal activation, is also increased in the spinal cord dorsal horn of CCI rats (Ro, L. S. *et al.*, 2004). Importantly, Fos protein expression is elevated throughout the dorsal horn (lamina I–VI) of the entire lumbar spinal cord, and like [^{14}C]-2-deoxyglucose activity, significant but lower increases were found in the contralateral dorsal horn. Thus, for both the [^{14}C]-2-deoxyglucose and Fos protein expression measures, there is a spread of neuronal activity to spinal regions outside of the normal central terminations of the sciatic nerve. This may explain why abnormal pain sensations are sometimes exhibited contralaterally, or in body areas that do not correspond with the terminations of an injured peripheral nerve (Koltzenburg, M. *et al.*, 1999; Ro, L. S. *et al.*, 2004).

In addition to enhanced spontaneous and evoked activity, spinal cord dorsal horn neurons of CCI rats are also found to have expanded receptive fields (Pitcher, G. M. and Henry, J. L., 2000). Rats with diabetic neuropathy following treatment with streptozotocin are also found to have dorsal horn neurons with high level of spontaneous activity and with expanded receptive fields (Chen, S. R. and Pan, H. L., 2002). A recent study measured dorsal horn neuronal activity in neuropathic pain patients undergoing surgery for ablation of the dorsal root entry zone (Guenot, M. *et al.*, 2003). These authors found similar alterations in dorsal horn neuron activity including bursting activity (in patients with deafferentation pain after brachial plexus avulsion) and nonrandom patterns of spontaneous discharge (in patients with peripheral nerve injury).

The enhanced spontaneous or evoked activity of dorsal horn neurons likely contribute to hyperalgesia and allodynia since systemic low-dose lidocaine reduces both spontaneous activity in WDR neurons (Sotgiu, M. L. *et al.*, 1992) and the thermal hyperalgesia (Abram, S. E. and Yaksh, T. L., 1994) in CCI rats. Mechanical allodynia induced by partial sciatic nerve lesion or SNL is also attenuated by i.t. treatment with very low doses of lidocaine that are not effective when given systemically (Ma, W. *et al.*, 2003a). The hyperalgesia after CCI depends partly on an injury discharge at the time of surgery, since the onset of thermal hyperalgesia in CCI rats was delayed by treating the nerve with bupivacaine 15 min before, but not 15 min after nerve constriction (Yamamoto, T. *et al.*, 1993).

5.26.1.2.5 Spinal cord injury

Animal models of central pain have been generated following traumatic, inflammatory, or excitotoxic injury of the spinal cord (see Vierck, C. J. and Light, A. R., 2000 or Yezierski, R. P., 2000 for reviews). Traumatic (Christensen, M. D. *et al.*, 1996; Christensen, M. D. and Hulsebosch, C. E., 1997; Bruce, J. C. *et al.*, 2002), inflammatory (Cahill, C. M. *et al.*, 1998), and excitotoxic (Yezierski, R. P. *et al.*, 1998) injury of spinal cord produces mechanical and thermal allodynia and/or hyperalgesia in rat hind paws. Spinal cord injury also results in a sensitization of spinal cord dorsal horn neurons as indicated by increased spontaneous activity, increased evoked responses to mechanical stimuli, and increased duration of after-discharges and enhanced windup (Yezierski, R. P. and Park, S. H., 1993; Christensen, M. D. and Hulsebosch, C. E., 1997; Wang, J. *et al.*, 2005; Zhang, H. *et al.*, 2005). It was recently demonstrated that spinal sensitization (enhanced spontaneous and evoked activity and enhanced windup in dorsal horn neurons), as well as hind paw thermal and mechanical allodynia, are reduced in spinal cord injured rats that are treated spinally with bupivacaine at the time of the injury (Zhang, H. *et al.*, 2005), suggesting that spinal sensitization underlies the development of allodynia/hyperalgesia after spinal cord injury. Spinal treatment with morphine also reduces the enhanced mechanically evoked responses of WDR neurons in the spinal cord dorsal horn of spinal cord injured rats (Wang, J. *et al.*, 2005). Consistent with these findings, it has recently been shown that central pain (spontaneous pain, mechanical allodynia, and/or mechanical hyperalgesia) associated with spinal cord injury in

rats is reduced by intravenous lidocaine administration (Attal, N. *et al.*, 2000; Finnerup, N. B. *et al.*, 2005).

5.26.1.2.6 Illness-induced hyperalgesia

Thermal hyperalgesia is also induced by intraperitoneal (i.p.) injection of agents that induce illness including lithium chloride and the bacterial cell wall endotoxin lipopolysaccharide (LPS) (Wiertelak, E. P. *et al.*, 1994; Watkins, L. R. *et al.*, 1994a). Illness-induced hyperalgesia has been shown to be dependent on spinal mechanisms that are activated by a descending pain facilitatory pathway (see below) that projects from the nucleus raphe magnus (NRM) through the dorsolateral funiculus to the spinal cord dorsal horn. The NRM has also been shown to be activated by brain regions that receive inputs from hepatic vagal afferent nerves (Watkins, L. R. *et al.*, 1994b).

5.26.1.2.7 Chronic opiate exposure

Thermal and/or mechanical hyperalgesia are observed in rats after repeated high-dose morphine treatment (Kayan, S. *et al.*, 1971; Mao, J. and Mayer, D. J., 2001) or in some cases after administration of low doses of morphine (Holtman, J. R., Jr. and Wala, E. P., 2005). This phenomenon mirrors a trend that has been observed in clinics in which chronic pain patients are treated with morphine (Jacobsen *et al.*, 1995). Mao J. *et al.* (1995a) and Mayer D. J. *et al.* (1999) have noted a parallel between hyperalgesia that occurs after repeated morphine exposure and that produced by neuropathic injury, each causing the activation of similar intracellular signaling pathways and the appearance of dark neurons in spinal cord dorsal horn. It is also significant that expression of the transcription factor Fos, which is commonly used as an indicator of neuronal activation, is upregulated in the spinal dorsal horn of rats that are morphine dependent and have withdrawal precipitated by injection of naltrexone (Rohde, D. S. *et al.*, 1996).

5.26.2 Alterations in Spinal Cord Dorsal Horn

5.26.2.1 Alterations in Transmitter or Growth Factor Expression or Release

5.26.2.1.1 Neuropeptides

Several lines of evidence suggest that C-fiber neuropeptides are involved in triggering CNS plasticity following injury or noxious stimulation. A role for C-fiber neuropeptides in nociception is suggested as noxious stimulation or peripheral inflammation causes the release of substance P (SP) (Go, V. L. and Yaksh, T. L., 1987; Oku, R. *et al.*, 1987; Duggan, A. W. *et al.*, 1988), neurokinin (NK) A (Hua, X. Y. *et al.*, 1986; Duggan, A. W. *et al.*, 1990), somatostatin (Kuraishi, Y. *et al.*, 1985; Morton, C. R. *et al.*, 1988), calcitonin gene-related peptide (CGRP) (Saria, A. *et al.*, 1986), dynorphin 1–17 (Parra, M. C. *et al.*, 2002), and galanin (Morton, C. R. and Hutchison, W. D., 1990; Colvin, L. A. and Duggan, A. W. *et al.*, 1998) in spinal cord dorsal horn. Spontaneous and noxious stimulus-evoked release of neuropeptide Y (NPY) is enhanced in the dorsal horn of rats with CCI of the sciatic nerve (Mark, M. A. *et al.*, 1998). Furthermore, the iontophoretic application of SP and other NKs produces an excitation of dorsal horn neurons (Henry, J. L., 1976; Willcockson, W. S. *et al.*, 1984a), while i.t. treatment produces behavioral hyperalgesia (Moochhala, S. M. and Sawynok, J., 1984; Cridland, R. A. and Henry, J. L., 1986) or nociceptive behaviors (Hylden, J. L., and Wilcox, G. L., 1981; Seybold, V. S. *et al.*, 1982; Gamse, R. and Saria, A., 1986) in rodents.

There is a decrease in immunoreactive staining for the neuropeptides SP and CGRP in the superficial dorsal horn of rats with experimental arthritis (Sluka, K. A. *et al.*, 1992). While the decrease in these neuropeptides occurs early (4–8 h) after knee inflammation, substance P and CRGP are increased after 5–7 days in the dorsal root ganglia and spinal cord of rats with inflammation of the knee (Sluka, K. A. and Westlund, K. N., 1993) or hind paw (Donnerer, J. *et al.*, 1993). Conversely, and spinal cord dorsal horn substance P and CGRP are decreased in the weeks after CCI of the sciatic nerve (Cameron, A. A. *et al.*, 1991). There is also a decrease in both mRNA and peptide levels of SP, somatostatin and CGRP in the DRG after peripheral nerve section (Jessell, T. M. *et al.*, 1979; Nielsch, V. *et al.*, 1987; Noguchi, K. *et al.*, 1989, 1990, 1993; Henken, D. B. *et al.*, 1990; Baranowsli, A. P. *et al.*, 1993), whereas the levels of cholecystokinin (CCK), galanin, pituitary adenylate cyclase activating peptide (PACAP), vasoactive intestinal polypeptide (VIP) and NPY are increased (Shehab, S. A. and Atkinson, M. E., 1986; Hokfelt, T. *et al.*, 1987; Villar, M. J. *et al.*, 1989; Noguchi, K. *et al.*, 1989, 1993; Wakisaka, S. *et al.*, 1991, 1992; Zhang, X. *et al.*, 1993b, Zhang, Y. Z., 1996). Dynorphin mRNA is also increased in the spinal dorsal horn following traumatic spinal cord injury (Tachibana, T. *et al.*, 1998).

For SP, the decreased immunoreactivity may reflect increased neuropeptide release since *in vivo* microdialysis studies show that spinal SP is increased

following partial sciatic nerve ligation (Wallin, J. and Schott, E., 2002). The increased levels of galanin may play an antinociceptive role as galanin overexpressing mice have attenuated mechanical and heat hyperalgesia after partial ischemic injury (Hygge-Blakeman, K. *et al.*, 2004) or CCI (Eaton, M. J. *et al.*, 1999) of the sciatic nerve. Spinal administration of galanin also produces an inhibition of dorsal horn neuronal responses to natural and electrical stimuli in rats with SNL (Flatters, S. J. *et al.*, 2002). In contrast, galanin knockout mice have attenuated responses to hind paw formalin injections (Kerr, B. J. *et al.*, 2001a), and have reduced thermal hyperalgesia after intraplantar injection of carrageenan (Kerr, B. J. *et al.*, 2001a) or partial sciatic nerve transection (Kerr, B. J. *et al.*, 2000). In addition, both windup and the facilitation of spinal reflexes following conditioning stimulation are significantly reduced in galanin knockout mice with sciatic nerve transections (Kerr, B. J. *et al.*, 2001b). Upregulated CCK may contribute to mechanical hypersensitivity as allodynia induced by spinal ischemic injury is reduced following administration of a CCK-B receptor antagonist (Wiesenfeld-Hallin, Z. *et al.*, 1997). Prodynorphin knockout mice or mice receiving dynorphin A antisera do not develop mechanical and thermal hyperalgesia after SNL (Gardell, L. R. *et al.*, 2004), suggesting that upregulated dynorphin contributes to nerve injury-induced hyperalgesia. Indeed, elevated spinal dynorphin content associated with SNL has been demonstrated to be coincident with the onset of mechanical allodynia and thermal hyperalgesia (Malan, T. P. *et al.*, 2000). Although the release of both VIP and NPY are elevated in the deep dorsal horn of rats with spinal nerve transection, the increases do not appear to be related to neuropathic pain as increases were observed even in rats that did not exhibit behavioral signs of hyperalgesia (Kim, H. J. *et al.*, 2003).

A role of C-fiber neuropeptides in noxious stimulus-induced plasticity is further suggested by several findings. Repetitive stimulation of dorsal roots elicits a slow depolarization in dorsal horn neurons which is mimicked by SP (Murase, K. and Randic, M., 1984), NK A (Murase, K. *et al.*, 1989), CGRP (Ryu, P. D. *et al.*, 1988), VIP (Urban, L. and Randic, M., 1984), or CCK (Murase, K. *et al.*, 1987), and is blocked by SP antagonists or capsaicin applied to the tissue bath (Urban, L. and Randic, M., 1984). Iontophoretic application of neuropeptides, such as SP, produces enhanced dorsal horn neuron responses to noxious thermal and mechanical stimulation (Henry, J. L., 1976; Randic, M. and Miletic, V., 1977). Dorn horn neuronal LTP induced *in vivo* by high-intensity, high-frequency tetanic afferent nerve stimulation is blocked by i.v. administration of NK-1) or NK-2 antagonists (Liu, X. and Sandkuhler, J., 1997). Knockout of the preprotackykinin-A gene, from which SP and NKA are derived, results in a reduction in the time course over which dorsal horn WDR neurons are sensitized following mustard oil application to the mice hind paw, as well as a reduction in the magnitude of poststimulus discharges of WDR neurons (Martin, W. J. *et al.*, 2004).

The increased excitability in flexor efferents, induced either by C-fiber electrical stimulation or by the application of chemical irritants, is blocked by pretreatment of the sciatic and saphenous nerves with the C-fiber neurotoxin capsaicin (Woolf, C. J. and Wall, P. D., 1986) or by the SP antagonist spantide II (Wiesenfeld-Hallin, Z. *et al.*, 1990). I.t. application of the C-fiber neuropeptides SP (Woolf, C. J. and Wiesenfeld-Hallin, Z., 1986), NK A (Xu, X.-J. *et al.*, 1991), CGRP (Woolf, C. J. and Wiesenfeld-Hallin, Z., 1986), VIP (Wiesenfeld-Hallin, Z., 1987), somatostatin (Wiesenfeld-Hallin, Z., 1985), and galanin (Wiesenfeld-Hallin, Z. *et al.*, 1989) produces prolonged enhancements in the excitability of the flexion reflex.

In addition, the hyperalgesia that develops in the hind paw contralateral to a thermal injury is mimicked by i.t. treatment with SP and NKA, and reversed by pretreatment with a SP antagonist (Coderre, T. J. and Melzack, R., 1991). Subcutaneous injection of formalin, which elicits a persistent nociceptive response associated with central changes (Coderre, T. J. *et al.*, 1990), evokes an immediate, intense barrage of C-fiber afferent activity (McCall, W. D. *et al.*, 1996), and produces an increase in SP in the cerebrospinal fluid (Kuraishi, Y. *et al.*, 1989). Furthermore, nociceptive responses to formalin are significantly suppressed in rats pretreated with peptide (Murray, C. W. *et al.*, 1991) and nonpeptide (Yamamoto, T. and Yaksh, T. L., 1991; Yashpal, K. *et al.*, 1993) NK-1 receptor antagonists, as well as the C-fiber neurotoxin capsaicin (Dray A. and Dickenson, A. H., 1991). Finally, various nonpeptide NK-1 receptor antagonists attenuate allodynia and hyperalgesia that is evoked by CCI of the sciatic nerve (Cumberbatch, M. J. *et al.*, 1998; Cahill, C. M. and Coderre, T. J., 2002).

5.26.2.1.2 *Excitatory amino acids*

Additional evidence implicates a contribution of excitatory amino acids (EAAs) to injury-induced

neuroplasticity. EAAs have widespread activity in the CNS including the spinal cord (Watkins, J. C. and Evans, R. H., 1981; Davies, J. and Watkins, J. C., 1983) and thalamus (Eaton, S. A. and Salt, T. E., 1990). The role of EAAs in nociception is suggested since noxious stimulation or peripheral inflammation causes the release of glutamate and aspartate in spinal cord dorsal horn (Skilling, S. R. *et al.*, 1988; Sorkin, L. S. *et al.*, 1992). The dorsal horn synaptosomal level of EAAs is increased in rats with CCI of the sciatic nerve (Somers, D. L. and Clemente, F. R., 2002), and dorsal horn levels of EAAs are increased in rats with a plantar incision (Zahn, P. K. *et al.*, 2002) or CCI of the sciatic nerve (al-Ghoul, W. M. *et al.*, 1993; Kawamata, M. and Omote, K., 1996). Furthermore, iontophoretic application of EAAs produces an excitation of dorsal horn neurons (Curtis, D. R. and Watkins, J. C., 1960; Willcockson, W. S. *et al.*, 1984b; Schneider, S. P. and Perl, E. R., 1988), while i.t. treatment produces both behavioral hyperalgesia and spontaneous nociceptive behaviors (Aanonsen, L. M. and Wilcox, G. L., 1986; 1987).

A role of EAAs in noxious stimulus-induced plasticity is further suggested by several findings. The windup of dorsal horn neuron activity after frequency C-fiber stimulation is mimicked by the application of L-glutamate or *N*-methyl-D-aspartate (NMDA) (Gerber, G. and Randic, M., 1989), and blocked by application of either competitive (Dickenson, A. H. and Sullivan, A. F., 1987; Thompson, S. W. *et al.*, 1990) or noncompetitive (Davies, S. N. and Lodge, D., 1987; Thompson, S. W. *et al.*, 1990) NMDA antagonists. Iontophoretic application of EAAs produces receptive field changes in dorsal horn neurons (Zieglgansberger, W. and Herz, A., 1971), as well as enhanced dorsal horn neuron responses to nonnoxious and noxious mechanical stimulation (Aanonsen, L. M. *et al.*, 1990; Dougherty, P. M. and Willis, W. D., 1991). Dorsal horn neurons that are sensitized following peripheral tissue injury/inflammation show increased responsiveness to the iontophoretic application of EAAs (Dougherty, P. M. and Willis, W. D., 1992; Dougherty, P. M. *et al.*, 1992b), and exhibit a reduction in responsiveness or sensitization following intravenous administration of ketamine or iontophoretic application of NMDA antagonists (Schaible, H.-G. *et al.*, 1991), or the administration of α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) or NMDA antagonists to dorsal horn neurons by reverse microdialysis (Dougherty, P. M. *et al.*, 1992a).

I.t. administration of the EAAs L-glutamate or L-aspartate produces an increase in the excitability of flexor efferents (Woolf, C. J. and Wiesenfeld-Hallin, Z., 1986), while competitive or noncompetitve NMDA antagonists reduce the facilitation of flexion reflexes induced by electrical (C-fiber) stimulation or cutaneous application of the chemical irritant mustard oil (Woolf, C. J. and Thompson, S. W., 1991). Hyperalgesia that develops in the hind paw contralateral to a thermal injury is both mimicked following i.t. treatment with NMDA, and reversed by an NMDA receptor antagonist (Coderre, T. J. and Melzack, R. 1991). Studies in humans (Kristensen, J. D. *et al.*, 1992), show that i.t. treatment with the competitive NMDA receptor antagonist 3-(2-carboxypiperazin-4-yl)-propyl-1-phosphonic acid (CPP) abolished after-discharges and spreading pain and hyperalgesia (symptoms proposed to be associated with windup) in a patient with neuropathic pain.

A contribution of ionotropic glutamate receptors (iGluRs) to nociceptive processing was originally suggested by the ability of AMPA/kainate, and particularly NMDA, receptor antagonists to produce analgesic effects in both phasic and tonic nociceptive tests in rats (Cahusac, P. M. *et al.*, 1984; Nasstrom, J. *et al.*, 1992). In addition, AMPA antagonists have been found to produce an inhibition of miniature endplate potentials in dorsal horn neurons (Hori, Y. and Endo, K., 1992) and dorsal root potentials evoked by single shock C-fiber stimulation (Thompson, S. W. *et al.*, 1992). Furthermore, tetanic electrical stimulation of the primary afferent fibers *in vitro* (Randic, M. *et al.*, 1993) or *in vivo* (Liu, X. G. and Sandkuhler, J., 1995) induces a LTP of the C-fiber-evoked potentials in dorsal horn neurons that is prevented by superfusion with NMDA antagonists.

NMDA antagonists have been particularly effective at reducing persistent pain associated with central sensitization. The noncompetitive NMDA antagonist MK-801 reduces the hyperalgesia which develops in rats with peripheral neuropathy (Davar, G. *et al.*, 1991; Mao, J. *et al.*, 1992c) or adjuvant-induced inflammation (Ren, K. *et al.*, 1992) and reduces autotomy behavior in rats with peripheral nerve sections (Seltzer, Z. *et al.*, 1991). Various competitive and noncompetitive NMDA receptor antagonists reduce the enhanced after-discharges, windup, and thermal- and mechanical-evoked responses of spinal dorsal horn neurons in rats with SNL (Leem, J. W. *et al.*, 1996; Suzuki, R. *et al.*, 2001). MK-801 has been found to reduce the increases in intracellular calcium ion (Ca^{2+}) concentration in spinal dorsal horn slices of rats which had CCI of the sciatic nerve (Kawamata, M. and Omote, K., 1996), as well as reducing increased Fos protein expression in response to

nonnoxious mechanical stimulation of the hind paw of CCI rats (Kosai, K. *et al.*, 2001). MK-801 also reduces the adjuvant inflammation-induced expansion of the receptive fields of nociceptive neurons in spinal cord dorsal horn (Dubner, R. and Ruda, M. A., 1992). In humans, ischemic and postoperative pain is suppressed by subanesthetic doses of ketamine (Maurset, A. *et al.*, 1989), while in the rat the increased activity in dorsal horn in response to ischemia associated with femoral artery occlusion is inhibited by i.t. application of an NMDA antagonist (Sher, G. and Mitchell, D., 1990). Subcutaneous injection of formalin evokes an increased release of glutamate and aspartate in spinal cord dorsal horn (Skilling, S. R. *et al.*, 1988), while the sustained responses of spinal nociceptive cells to noxious peripheral stimulation produced by subcutaneous formalin injection are reduced by i.t. administration of selective NMDA antagonists (Haley, J. E. *et al.*, 1990). Nociceptive responses to formalin are also both enhanced by pretreatment with the EAA agonists, L-glutamate and L-aspartate, as well as combinations of NMDA + AMPA or NMDA + trans-1-aminocyclopentane-1,3-dicarboxylate (ACPD) (Coderre, T. J. and Melzack, R., 1992a), and suppressed by pretreatment with NMDA antagonists (Murray, C. W. *et al.*, 1991; Coderre, T. J. and Melzack, R., 1992a).

Evidence suggests that in addition to iGluRs, metabotropic glumate receptors (mGluRs) also play a significant role in nociception. Unlike iGluRs, which gate cation channels, mGluRs are coupled by G proteins to various intracellular messengers (Pin, J. P. and Duvoisin, R., 1995). Molecular cloning techniques have identified eight subtypes of mGluRs to date, some of which include splice variants (Pin, J. P. *et al.*, 1992; Hollmann, M. and Heinemann, S. F., 1994). The eight subtypes of mGluRs are divided into three groups based on sequence homology, signal transduction mechanisms, and ligand selectivites (Nakanishi, S., 1992). Group I includes mGluR1 and 5 which stimulate phospholipase C (PLC), leading to protein kinase C (PKC) activation, phosphoinositide (PI) hydrolysis, and intracellular Ca^{2+} mobilization (Houamed, K. M. *et al.*, 1991; Masu, M. *et al.*, 1991; Abe, T. *et al.*, 1992).

The nonselective mGluR antagonist L-AP3 attenuates rat dorsal horn neuronal activity associated with repeated mustard oil application (Young, M. R. *et al.*, 1994; 1995) and knee joint inflammation (Neugebauer, V. *et al.*, 1994). Furthermore, the nonselective mGluR agonists trans-ACPD or 1*S*,3*R*-ACPD produce a depolarization (Young, M. R. *et al.*, 1994; 1995) or increased evoked responses (Palecek, J. *et al.*, 1994) in dorsal horn neurons. 1*S*,3*R*-ACPD also produces a ventral root (VR) depolarization in neonatal rat spinal cord *in vitro* (Boxall, S. J. *et al.*, 1996; 1998). The VR depolarization produced by 1*S*,3*R*-ACPD and windup after stimulation of dorsal roots, or capsaicin application, are blocked by the mGluR antagonist (+/−)-alpha-methyl-4-carboxphenylglycine (MCPG) (Boxall, S. J. *et al.*, 1996).

Selective group I mGluR antagonists also reduce rat dorsal horn neuronal activity evoked by hind paw mustard oil (Boxall, S. J. *et al.*, 1996) or capsaicin (Neugebauer, V. *et al.*, 1999). Furthermore, dorsal horn neuronal activity is increased by spinal administration of the group I mGluR agonist dihydroxyphenylglycine (DHPG) (Young, M. R. *et al.*, 1997; Neugebauer, V. *et al.*, 1999); although see Chen Y. *et al.* (2000). DHPG may act primarily at mGluR1, as agonists of mGluR5 (*trans*-ADA, CHPG) have either less (Young, M. R. *et al.*, 1997) or no (Neugebauer, V. *et al.*, 1999) excitatory effects. However, 1*S*,3*R*-ACPD, DHPG, and CHPG all produce a long-lasting potentiation of polysynaptic EPSPs in dorsal horn cells receiving C-fiber afferent input (Zhong, J. *et al.*, 2000). The neuronal activation evoked by spinal DHPG, or hind paw application of mustard oil or capsaicin, is also reduced by mGluR1-selective antagonists (Young, M. R. *et al.*, 1997; Neugebauer, V. *et al.*, 1999). However, a selective mGluR5 antagonist 2-methyl-6-(phenylethynyl)-pyridine (MPEP) attenuates shock-induced VR potentials and windup in isolated spinal cords (Bordi, F. and Ugolini, A., 2000), as well as reducing the enhanced spontaneous and noxious-stimulus-evoked activity in spinal cord neurons of rats with CCI of the sciatic nerve (Sotgiu, M. L. *et al.*, 2003). Alternatively, group II and III mGluR agonists depress spinal reflexes or activity in isolated spinal cords (Saitoh, T. *et al.*, 1998; Gerber, G. *et al.* 2000; Krieger, P. and El Manira, A., 2002), and reverse the hypersensitivity of dorsal horn neurons after skin capsaicin treatment (Neugebauer, V. *et al.*, 2000) or SNL (Chen, S. R. and Pan, H. L., 2005).

Behavioral studies also suggest mGluRs influence nociception. I.t. quisqualate, an mGluR and AMPA receptor agonist, produces hyperalgesia (Aanonsen, L. M. *et al.*, 1990; Kolhekar, R. and Gebhart, G. F., 1994), as well as nociceptive behaviors (Sun, X. and Larson, A. A. 1991) in rodents. The mGluR agonist 1*S*,3*R*-ACPD (Fisher, K. and Coderre, T. J., 1996a)

produces similar behaviors, implicating mGluRs in these responses. Furthermore, nociceptive behaviors and hyperalgesia are also produced by i.t. DHPG (Fisher, K. and Coderre, T. J., 1996a; 1998; Dolan, S. and Nolan, A. M., 2000; Hama, A. T., 2003), but importantly, not by the selective mGluR5 agonist trans-ADA (Fisher, K. and Coderre, T. J., 1996a). This suggests a pronociceptive role of spinal mGluR1. Conversely, i.t. administration of trans-ACPD, and a group II mGluR agonist (L-CCG-I), produce increased mechanical withdrawal thresholds, that are blocked by a group II mGluR antagonist (Chen, S. R. and Pan, H. L., 2005). This suggests an antinociceptive role for group II mGluRs.

Group I mGluRs are also implicated in the development of hyperalgesia and persistent pain associated with inflammatory or chemical injury. Thus, nonselective and group I selective mGluR antagonists (Walker, K. *et al.*, 2001; Zhang, L. *et al.*, 2002; Zhu, C. Z. *et al.*, 2004), and group I mGuR antisense oligonucleotides (Fundytus, M. E. *et al.*, 2002) reduce hyperalgesia in rats with hind paw inflammation. Furthermore, formalin nociception is enhanced by spinal i.t. 1*S*,3*R*-ACPD (Coderre, T. J. and Melzack, R., 1992a) and DHPG (Fisher, K. and Coderre, T. J., 1996b), and nociception associated with hind paw formalin (Fisher, K. and Coderre, T. J., 1996b; Varty, G. B. *et al.*, 2005) and i.p. acetic acid injections are reduced by group I mGluR antagonists (Chen, Y. *et al.*, 2000; Zhu, C. Z. *et al.*, 2004). Formalin nociception is also reduced by group II and III mGluR agonists (Fisher, K. and Coderre, T. J., 1996b; Simmons, R. M. A. *et al.*, 2002), and by enhancing an endogenous group II mGluR agonist (Yamamoto, T. *et al.*, 2004). Thus, while Group I activation is nociceptive, activation of Group II or III mGluRs is antinociceptive. Indeed, group I mGluR-linked intracellular messengers (i.e., PKC, IP_3 (inositol trisphosphate), and $_{i}Ca^{2+}$) contribute to nociception (Igwe, O. J. and Ning, L., 1994; Mao, J. *et al.*, 1995b), while events linked to group II/III mGluR (i.e., decreased cyclic adenosine monophosphate (cAMP) production) produce antinociception (Gereau, R. W. and Conn, P. J., 1994; Shen, J. *et al.*, 2000).

mGluRs also influence hyperalgesia induced by nerve injury. Group I mGluR antagonists reduce hyperalgesia in CCI-injured rats (Fisher, K. *et al.*, 1998). CCI-induced hyperalgesia is also reduced by selective mGluR1 and mGluR5 antagonists (Fisher, K. *et al.*, 2002; Zhu, C. Z. *et al.*, 2004), as well as group II (2R,4R-APDC) and III (L-AP4) mGluR agonists (Fisher, K. *et al.*, 2002), and by antisense oligonucleotides to mGluR1 and mGluR5 (Fundytus, M. E. *et al.*, 2001). Hyperalgesia after SNL is reduced by group I mGluR antagonists (Dogrul, A. *et al.*, 2000; Zhu, C. Z. *et al.*, 2004; Varty, G. B. *et al.*, 2005) and group II and III agonists (Simmons, R. M. A. *et al.*, 2002; Chen, S. R. and Pan, H. L., 2005). Tactile allodynia after spinal cord injury is also reduced by the mGluR1 antagonist (RS)-1-aminoindan-1,5-dicarboxylic acid (AIDA) (Mills, C. D. *et al.*, 2000), as well as group II and III mGluR agonists (Mills, C. D. *et al.*, 2002). Group II (mGluR3,4) and group III (mGluR4, 6, 7, 8) result in reduced production of cyclic adenosine monophosphate (cAMP) (Schoepp, D. D. *et al.*, 1995; Tanabe, Y. et al., 1993).

5.26.2.1.3 Other transmitters

The expression of a variety of other transmitters are affected following inflammatory or nerve injuries that produce hyperalgesia and allodynia. Thus, there is a reduction in the number of gamma-aminobutyric acid (GABA)- and glutamate decarboxylase (GAD)-, the synthetic enzyme for GABA, immunoreactive cells in the spinal cord of rats with CCI of the sciatic nerve (Eaton, M. J. *et al.*, 1998). There is also a reduction in the level of GABA in spinal cord microdialysates taken form rats with a partial constriction of the sciatic nerve that exhibit allodynia (Stiller, C. O., *et al.*, 1996). Recent studies also indicate that there is a reduction in endomorphin-2 immunoreactivity in the superficial dorsal horn of mice with a partial ligation of the sciatic nerve, which paralleled the development of thermal hyperalgesia (Smith, R. R. *et al.*, 2001).

5.26.2.1.4 Neurotrophins

Neurotrophins (NTs) are growth factors which stimulate neuronal growth in embryonic development, and maintain neuronal viability in adult tissues. NTs include nerve growth factor (NGF) that acts selectively at tyrosine kinase receptor A (TrkA), brain-derived neurotrophic factor (BDNF), NT-4, and NT-5, which act at TrkB receptors, and NT-3 that acts at TrkC receptors in spinal cord. An additional NT, glial-derived neurotrophic factor (GDNF), binds to the receptor GFR-alpha1. Small diameter unmyelinated primary afferent fibers generally fall into two groups: one which contains CGRP, SP, and TrkA receptors, and depends on NGF for its development; a second contains the lectin IB-4 and TrkB receptors, and is dependent on GDNF for its

development (McMahon, S. B. *et al.*, 1994). Importantly, these neurotrophic factors are not only required for neuronal development; they continue to be produced by numerous types of cells, produce excitatory effects on primary afferent fibers, and are required to maintain normal neuronal function of primary afferent fibers. BDNF has been found to be expressed in primary afferent fibers (particularly C fibers containing CGRP and SP) (Barakat-Walter, I., 1996), and to act in the spinal cord to enhance neuronal excitability (Kerr, B. J. *et al.*, 1999; Thompson, S. W. *et al.*, 1999).

It has been hypothesized that hyperalgesia after inflammatory injury is influenced by an upregulation of BDNF in primary afferent fibers that occurs in response to peripheral stimulation of primary afferent fibers with NGF (Thompson, S. W. *et al.*, 1999). Thus, inflammation leads to increased production of NGF in peripheral tissue, which stimulates TrkA receptors on the first group of primary afferent fibers (peptidergic fibers) described above (Apfel, S. C., 2000). The stimulation of TrkA receptors results in increased BDNF production in this group of C fibers (Apfel, S. C. *et al.*, 1996; Michael, G. J. *et al.*, 1997), and precipitates enhanced BDNF release, and a subsequent sensitization of dorsal horn neurons (Thompson, S. W. *et al.*, 1999). Noxious thermal, mechanical, and chemical stimuli, but not innocuous stimuli, also causes activation of spinal TrkB receptors as shown by increased Trk phosphorylation and increased extracellular signal-regulated kinase (ERK) activation (see below) in dorsal horn, which is blocked by sequestering BDNF with a TrKB–IgG fusion molecule (Pezet, S. *et al.*, 2002).

Importantly, BDNF protein and mRNA expression is increased in rat DRG and spinal dorsal horn following hind paw injection of CFA (Cho, H. J. *et al.*, 1997a; 1997b). BDNF protein levels are increased in DRG and spinal cord dorsal after CCI of the sciatic nerve (Ha, S. O. *et al.*, 2001; Miletic, G. and Miletic, V., 2002), while BDNF mRNA and or protein is also increased in uninjured L4 DRG and dorsal horn following L5 SNL (Fukuoka, T. *et al.*, 2001; Ha, S. O. *et al.*, 2001). I.t. administration of antibodies to BDNF attenuate thermal hyperalgesia in rats with L5 SNL (Fukuoka, T. *et al.*, 2001), while BDNF antisense olgionucleotides and the BDNF-scavenging protein TrkB–IgG attenuates carrageenan-induced thermal hyperalgesia (Kerr, B. J. *et al.*, 1999; Groth, R. and Aanonsen, L. M., 2002). Conversely, i.t. administration of BDNF and NT-4/5, which act at TrkB, but not the TrkC agonist NT-3, produce thermal hyperalgesia, while antisense to TrkB attenuates carrageenan-induced thermal hyperalgesia in rats (Groth, R. and Aanonsen, L. M., 2002). In contrast, antisense oliginucleotides to NT-3 have been found to attenuate mechanical allodynia in rats with partial sciatic nerve ligation (White, D. M., 2000). Alternatively, rats intrathecally treated with adenovirus to produce a spinal cord overexpression of BDNF (Eaton, M. J. *et al.*, 2002), or transgenic mice that overexpress NT-3 in muscle (Gandhi, R. *et al.*, 2004), each exhibit reduced mechanical allodynia and thermal hyperalgesia, after CCI of the sciatic nerve or acid injection into the gastrocnemius muscle, respectively. Protein and mRNA levels of GDNF and GFRα-1 are significantly increased in DRGs of rats with CCI of the sciatic nerve, and thermal hyperalgesia in CCI rats is significantly enhanced by i.t. administration of GFRα-1 antisense oligonucleotides, suggesting that GDNF may act at GFRα-1 to produce antihyperalgesic effects (Dong, Z. Q. *et al.*, 2005).

5.26.2.1.5 Phenotype switch

Evidence suggests that specific primary afferent fibers may be able to switch their phenotype following intense noxious stimulation. Thus, it has been shown that after inflammatory injury Aβ fibers begin to produce and release SP (which they normally do not contain) (Neumann, S. *et al.*, 1996); a phenomenon that has important implications for the development of mechanical allodynia (which is believed to mediated largely by Aβ fibers). Evidence suggests that growth factors or NTs may play a critical role in the development of these injury-induced phenotype changes (Woolf, C. J., 1996). The NT BDNF itself has been shown to undergo a phenotype switch after nerve injury as there is a shift in the size distribution of rat DRG neurons that contain BDNF after sciatic nerve lesions, so that large neurons, which do not initially express BDNF, start to express more than small neurons (Zhou, X. F. *et al.*, 1999a). Large DRG neurons also exhibit a phenotype switch when they start to express both BDNF (Ohtori, S. *et al.*, 2002) and CGRP (Ohtori, S. *et al.*, 2001) after CFA-induced inflammation of the lumbar facet joint.

5.26.2.2 Expression of Second Messengers and Transcription Factors

5.26.2.2.1 Second messengers

A growing body of literature suggests that intracellular messengers linked with various ionotropic and metabotropic receptors contribute to synaptic

plasticity in spinal cord dorsal horn. Ca^{2+} is a key intracellular messenger that is elevated in the cytoplasm of neurons following influx through receptor-operated and voltage-gated Ca^{2+} channels, or following release from intracellular stores. Glutamate and aspartate stimulate the influx of Ca^{2+} through NMDA receptor-operated channels (MacDermott, A. B. *et al.*, 1986). SP produces an elevation in intracellular Ca^{2+} by mobilizing its release from intracellular stores (Womack, M. D. *et al.*, 1988), while both SP (Womack, M. D. *et al.*, 1989) and CGRP (Oku, R. *et al.*, 1988) increase Ca^{2+} influx through voltage-gated Ca^{2+} channels. Activity at either NK-1 receptors by SP (Mantyh, P. W. *et al.*, 1984), or at metabotropic EAA receptors by glutamate and aspartate (Sugiyama, H. *et al.*, 1987), stimulates the hydrolysis of inositol phospholipids by activating a polyphosphoinositide-specific PLC. PLC is an enzyme which catalyzes the hydrolysis of polyphosphatidylinositol into the intracellular messengers IP_3 and diacylglycerol (DAG). Following its production, IP_3 stimulates the release of Ca^{2+} from internal stores; on the other hand, DAG stimulates the translocation and activation of PKC.

Gerber G. *et al.* (1989) showed that activators of PKC enhance the basal and evoked release of glutamate and aspartate in the spinal cord slice, as well as the depolarizing responses of dorsal horn neurons to exogenous glutamate and NMDA. Furthermore, Chen L. and Huang L.-Y. M. (1992) demonstrated that PKC increases NMDA-activated currents in isolated trigeminal cells by increasing the probability of channel openings and by reducing the voltage-dependent Mg^{2+} block of NMDA receptor channels. PKC is involved in synaptic plasticity causing a phosphorylation of both group I mGluR (Alaluf, S. *et al.*, 1995) and NMDA receptors (Chen, L. and Huang, L.-Y. M., 1992). Enhanced spinal PKC activity is observed following inflammatory (Yashpal, K. *et al.*, 1995; 2001; Sweitzer, S. M. *et al.*, 2004b) and nerve injury (Mao, J. *et al.*, 1992b; Miletic, V. *et al.*, 2000; Fundytus, M. E. *et al.*, 2001; Yashpal, K. *et al.*, 2001) and PKC inhibitors reduce pain induced by hind paw injection of noxious chemicals (Yashpal, K. *et al.*, 1995; 2001; Li, K. C. and Chen, J., 2003; Sweitzer, S. M. *et al.*, 2004b) and nerve injury (Hua, X. Y. *et al.*, 1999b; Miletic, V. *et al.*, 2000; Yajima, Y. *et al.*, 2003). PKC also enhances NMDA receptor activity (Liao, G. Y. *et al.*, 2001; Skeberdis, V. A. *et al.*, 2001) and NMDA receptor trafficking to neuronal plasma membranes (Lan, J. Y. *et al.*, 2001). PKC has several different isoforms, and evidence suggests that PKCγ is increased in the rat spinal cord dorsal horn after CCI of the sciatic nerve (Mao, J. *et al.*, 1995b), and the synaptosomal membrane fraction of both PKCγ and PKCβ-II is increased in the spinal cord dorsal of CCI rats (Miletic, V. *et al.*, 2000). Importantly, PKCγ knockout mice exhibit reduced mechanical allodynia and thermal hyperalgesia after partial sciatic nerve ligation (Malmberg, A. B. *et al.*, 1997a). PKCε is also upregulated in rat DRG following hind paw injections of carrageenan or CFA, in a manner that is correlated with the development of inflammatory hyperalgesia (Zhou, Y. *et al.*, 2003).

Increased neuronal Ca^{2+} infux also activates phospholipase A2 that triggers the production of arachidonic acid (Dumuis, A. *et al.*, 1988; 1990), which is metabolized into various eicosanoids, including prostaglandins (PGs). Further increases in arachidonic acid occur following the breakdown of DAG (Gammon, C. M. *et al.*, 1989), which is produced following stimulation of PLC with activity at various metabotropic receptors. Spinal administration of PGE_2 enhances the responsiveness and receptive field sizes of rat spinal dorsal horn neurons (Vasquez, E. *et al.*, 2001), as well as producing mechanical allodynia and thermal hyperalgesia in mice (Minami, T. *et al.*, 1994a; 1994b). There is an increase in the levels of PGE_2 in CSF of rat after knee joint injection of carrageenan/kaolin (Yang, L. C. *et al.*, 1996) or i.t. injection of SP (Hua, X. Y. *et al.*, 1999a). The breakdown of arachidonic acid into PGs in inhibited by nonsteroidal anti-inflammatory drugs (NSAIDs), and i.t. administration of NSAIDs produces analgesia in animals subjected to i.p. acetic acid or hind paw formalin injections (Yaksh, T. L., 1982; Malmberg, A. B. and Yaksh, T. L., 1992a), as well as reducing enhanced flexor reflexes in rats with hind paw injections of CFA (Seybold, V. S. *et al.*, 2003). I.t. NSAIDs block thermal hyperalgesia induced by i.t. treatment with NMDA or SP (Malmberg, A. B. and Yaksh, T. L., 1992b). There is also an elevation of the enzyme cyclooxygenase-2 (COX-2) in the spinal CSF of rats with hind paw carrageenan injections (Ibuki, T. *et al.*, 2003) or in the spared nerve injury model (Broom, D. C., *et al.*, 2004). Furthermore, thermal hyperalgesia associated with carrageenan injection is attenuated by i.t. treatment with a selective inhibitor of COX-2 (Dirig, D. M. *et al.*, 1998; Ibuki, T. *et al.*, 2003), but not COX-1 (Yaksh, T. L. *et al.*, 2001). I.t. COX-2 inhibitors are found to relieve hyperalgesia in a model of hind paw inflammation, but not in the spared nerve injury model (Broom *et al.*, 2004).

Elevation in intracellular Ca^{2+} in neurons also leads to increases in additional protein kinases such as Ca^{2+}/calmodulin-dependent protein kinase (CaMK) (Kennedy, M. B. *et al.*, 1983). There is an increased expression and phosphorylation of CaMK-II in rat spinal cord dorsal horn after hind paw injection of capsaicin, while i.t. administration of a CaMK-II inhibitor reduces enhanced dorsal horn neuronal responsiveness and behavioral responses after hind paw capsaicin (Fang, L. *et al.*, 2002), as well as reducing mechanical allodynia and thermal hyperalgesia in CCI mice (Garry, E. M. *et al.*, 2003). Mice with a mutation of the alpha-CaMK-II gene, which prevents autophosphorylation of CaMK-II, also have diminished nociceptive responses to hind paw formalin injections (Zeitz, K. P. *et al.*, 2004).

The binding of Ca^{2+} to calmodulin activates nitric oxide (NO) synthase, which generates NO from free L-arginine (Garthwaite, J. *et al.*, 1988), which in turn activates soluable guanylate cyclase and increases cGMP (Southam, E. *et al.*, 1991). Intracellularly the Ca^{2+} binds to calmodulin which activates NO synthase. NO synthase converts L-arginine to NO, and the released NO stimulates the production of cGMP from soluable guanylate cyclase (Synder, S. H., 1992). The levels of neuronal NO synthase, as well as NADPHd and [^{3}H]citrulline staining (markers of NO activity), are increased in the rat DRG and spinal cord dorsal horn after CCI or transection of the sciatic nerve (Cizkova, D. *et al.*, 2002a; Lukacova, N. *et al.*, 2003), SNL (Steel, J. H., *et al.*, 1994), or hind paw formalin injection (Lam, H. H. *et al.*, 1996). There is also increased cGMP in the spinal dorsal horn of rats with CCI of the sciatic nerve that parallels the development of mechanical allodynia and thermal hyperalgesia (Siegan, J. B. *et al.*, 1996). In addition, NO synthase inhibitors or an inhibitor of soluable guanylate cyclase reduce the thermal hyperalgesia that develops in rats with chronic nerve constriction injury (Meller, S. T. *et al.*, 1992) or hind paw carrageenan (Meller, S. T. *et al.*, 1994; Osborne, M. G. and Coderre, T. J., 1999).

Mediators such as NO, which increase neuronal cGMP, stimulate the production of cAMP-dependent protein kinase (PKG) (Scott, J. D., 1991). The spinal dorsal horn levels of PKG1α are increased in response to hind paw injection of formalin, and i.t. administration of PKG inhibitors reduces nociceptive responses to formalin (Tao, Y. X. *et al.*, 2000; Schmidtko, A. *et al.*, 2003). I.t. treatment with a PKG inhibitor also reverses mechanical allodynia observed in rats with a hind paw injection of capsaicin (Sluka, K. A. and Willis, W. D., 1997), and thermal hyperalgesia induced by i.t. injections of NMDA or an NO donor (Tao, Y. X. and Johns, R. A., 2000). I.t. administration of a PKG activator produces mechanical allodynia which is absent in PKG-I knockout mice, further implicating a role for spinal PKG in allodynia (Tegeder, I. *et al.*, 2004a).

Activity at various neuropeptide receptors leads to increased levels of adenylate cyclase in spinal cord neurons (see Millan, M. J., 1999 for a review). The enzyme adenylate cyclase increases cAMP and its associated kinase, protein kinase A (PKA), which causes membrane phosphorylation that enhances Na^+ and Ca^{2+} currents, and decreases K^+ currents in primary afferent fibers (Vanegas, H. and Schaible, H. G., 2001). Enhancing the spinal cord levels of PKA leads to a sensitization of dorsal horn neurons to noxious mechanical stimulation (Lin, Q. *et al.*, 2002), and i.t. administration of PKA inhibitors attenuate the mechanical allodynia induced by hind paw injection of capsaicin (Sluka, K. A. and Willis, W. D., 1997). There is also a reduction in thermal hyperalgesia associated with hind paw inflammation in mice with a target mutation of the type I regulatory subunit of PKA (Malmberg, A. B. *et al.*, 1997b).

Activity of growth factors and various hormones leads to the activation of a mitogen-activated protein kinase (MAPK) pathway through stimulation of a GTP-binding protein Ras and protein kinases, such as PKC (Davis, R. J., 1993). A growing body of literature suggests that MAPK, including ERK, p38 MAPK, and c-Jun N-terminal kinase (JNK) contribute to spinal nociceptive processing. Recent studies have shown ERK activity is observed in lamina I and IIo of the ipsilateral dorsal horn after noxious thermal stimulation of the hind paw or C-fiber electrical nerve stimulation, but not after nonnoxious thermal or A fiber electrical stimulation (Ji, R. R. *et al.*, 1999). ERK activity is also observed in rodent DRG or spinal cord dorsal horn in response to hind paw injections of carrageenan (Galan, A. *et al.*, 2002), CFA (Ji, R. R. *et al.*, 2002a, Obata, K. *et al.*, 2003), formalin (Ji, R. R. *et al.*, 1999, Karim, F. *et al.*, 2001), or capsaicin (Ji, R. R. *et al.*, 1999), or to sciatic nerve transection (Obata, K. *et al.*, 2003), CCI (Obata, K. *et al.*, 2004a) partial sciatic nerve ligation (Ma, W. and Quirion, R., 2002) or L5 SNL (Obata, K. *et al.*, 2004b). Inhibitors of ERK have been found to reduce nociception induced by formalin (Ji, R. R. *et al.*, 1999, Karim, F. *et al.*, 2001), and hyperalgesia or allodynia after hind paw injection of carrageenan (Sammons, M. J. *et al.*, 2000), CFA (Ji, R. R. *et al.*, 2002a) or

capsaicin (Kawasaki, Y. *et al.*, 2004), and in rats with CCI of the sciatic nerve (Ciruela, A. *et al.*, 2003) or L5 SNL (Obata, K. *et al.*, 2004b). Recently, it has been shown that stimulation of group I mGluRs leads to activation of ERK in spinal cord dorsal horn, and that antagonists of group I mGluRs produce a reduction in formalin-stimulated ERK activation (Karim, F. *et al.*, 2001). Adwanikar, H. *et al.* (2004) has also shown that ERK inhibitors significantly reduce DHPG-induced spontaneous nociceptive behaviors (SNBs) in mice that have received a prior hind paw injection of CFA.

Recent evidence indicates there is an increase in phosphorylated p38 MAPK in DRG neurons and microglia of the DRG and spinal cord following hind paw injection of formalin (Kim, S. Y. *et al.*, 2002) or capsaicin (Sweitzer, S. M. *et al.*, 2004a; Mizushima, T. *et al.*, 2005) or CCI of the sciatic nerve (Kim, S. Y. *et al.*, 2002; Obata, K. *et al.*, 2004a). I.t. treatment with a p38 MAPK inhibitor reverses thermal hyperalgesia produced by hind paw capsaicin injection (Sweitzer, S. M. *et al.*, 2004a; Mizushima, T. *et al.*, 2005) or in CCI rats (Obata, K. *et al.*, 2004a). There is also increased p38 MAPK activity in neurons of both the injured L5 and the uninjured L4 DRG after L5 SNL, and i.t. treatment with a p38 MAPK inhibitor reverses mechanical allodynia and thermal hyperalgesia in L5 SNL rats (Obata, K. *et al.*, 2004b). In contrast, JNK activity is increased only in L5 DRG neurons after L5 SNL, and i.t. administration of a JNK inhibitor reverses only mechanical allodynia in rats with L5 SNL (Obata, K. *et al.*, 2004b). JNK activity is also increased in the spinal cord dorsal horn of rats with partial sciatic nerve ligation (Ma, W. and Quirion, R., 2002).

It is now evident that activity of the NMDA receptor is regulated by the protein tyrosine kinases (PTKs), Src and Fyn, which phosphorylate the NMDA channel and enhance its activity (Yu, X. M. *et al.*, 1997; Tezuka, T. *et al.*, 1999; Yu, X. M. and Salter, M. W., 1999). Evidence that this process might contribute to hyperalgesia after nerve injury is suggested as phosphotyrosine staining is increased in the spinal cord dorsal horn following sciatic nerve transection (Eckert, W. A. *et al.*, 1994). Furthermore, i.t. administration of nonselective PTK inhibitors, reduce hind paw mechanical and thermal hyperalgesia produced by injection of carrageenan and kaolin to the base of the rat tail, or following i.t. injection of NMDA (Sato, E. *et al.*, 2003), as well as reducing thermal hyperalgesia in rats with partial sciatic nerve ligation (Yajima, Y. *et al.*, 2002). I.t. treatment with a selective Src inhibitor delays the onset of mechanical allodynia and hyperalgesia induced by hind paw injection of CFA (Guo, W. *et al.*, 2002), as well as reducing capsaicin-induced ERK activation in spinal cord slices (Kawasaki, Y. *et al.*, 2004). In contrast to the effects of PTKs, NMDA receptors currents have been shown to be inhibited by protein tyrosine phosphatases (PTPs) (Wang, Y. T. *et al.*, 1996). Recent studies have shown that i.t. administration of PTP inhibitors produces an enhancement of mechanical allodynia and hyperalgesia induced by hind paw injection of capsaicin (Zhang, X. *et al.*, 2003). Studies using selective inhibitors or antisense oligonucleotides have also implicated various other kinases including: IkappaB kinase (Tegeder, I. *et al.*, 2004b), cyclin-dependent kinase 5 (Cdk5) (Wang, C. H. *et al.*, 2005), and Rho kinase (Tatsumi, S. *et al.*, 2005) in nociception or hyperalgesia associated with hind paw formalin or zymosan injection or CCI of the sciatic nerve.

5.26.2.2.2 Transcription factors

Noxious stimulation leads to the expression of proto-oncogenes and their protein products which act as transcription factors. Hunt S. P. *et al.* (1987) first demonstrated that the c-fos protein product Fos is expressed in postsynaptic dorsal horn neurons following noxious thermal or chemical stimulation of the skin. The expression of Fos has also been demonstrated in rat spinal dorsal horn in response to noxious pinch of the hind paws (Bullitt, E., 1989), the injection of formalin (Presley, R. W. *et al.*, 1990) or carrageenan (Draisci, G. and Iadorola, M. J., 1989) into a hind paw or sodium urate crystals into joints (Menétrey, D. *et al.*, 1989), the injection of acetic acid into viscera (Menétrey, D. *et al.*, 1989), the induction of polyarthritis with CFA (Menétrey, D. *et al.*, 1989). Fos expression in the rat spinal dorsal horn is also increased after transection (Chi, S. I. *et al.*, 1993), CCI (Kajander, K. C. *et al.*, 1996; Catheline, G. *et al.*, 1999) or partial ligation (Delander, G. E. *et al.*, 1997) of the sciatic nerve. Importantly, there is a strong correlation between pain behavior and the number of cells expressing Fos (Presley, R. W. *et al.*, 1990). The time course of Fos expression after peripheral inflammation (Draisci, G. and Iadorola, M. J., 1989) or nerve injury (Delander, G. E. *et al.*, 1997) has been found to be correlated with the development of hyperalgesia. Moreover, morphine pretreatment produces a dose-dependent suppression of Fos expression which corresponds with its analgesic effects (Presley, R. W. *et al.*, 1990; Tolle, T. R. *et al.*, 1990).

An increase in phosphorylated cyclic AMP response element binding (pCREB) protein is observed in the spinal cord dorsal horn of rats with partial ligation or CCI of the sciatic nerve (Ma, W. and Quirion, R., 2001; Miletic, G. *et al.*, 2002, 2004b) or hind paw injections of capsaicin (Kawasaki, Y. *et al.*, 2004; Fang, L. *et al.*, 2005). Elevation in spinal pCREB associated with nerve injury, hind paw capsaicin, or electrical nerve stimulation has been found to be dependent on the activation of PKA, PKC, ERK, or CaMK (Kawasaki, Y. *et al.*, 2004; Miletic, G. *et al.*, 2004b; Fang, L. *et al.*, 2005; Miyabe, T. and Miletic, V., 2005). I.t. treatment with antisense oligonucleotides to CREB reduces the mechanical allodynia in rats with partial sciatic nerve ligation (Ma, W. *et al.*, 2003b).

Noxious stimulation, inflammatory, or nerve injury also leads to the spinal cord expression of other transcription factors, including Fos B, Jun, Jun B, Jun C, Jun D (Herdegen, T. *et al.*, 1991a; 1991b; Delander, G. E. *et al.*, 1997), NGFI-A/Krox 24, NGFI-B, serum response factor (Herdegen, T. *et al.*, 1990; Wisden, W. *et al.*, 1990), FRA-1, FRA-2 (Munglani, R. and Hunt, S. P., 1995), AP-1, nuclear factor kappa B, octamer factors (Chan, C. F. *et al.*, 2000; Pollock, G. *et al.*, 2005), activating transcription factor 3 (Tsujino, H. *et al.*, 2000), cyclic AMP responsive element modulator (Naranjo, J. R. *et al.*, 1997), and peroxisome proliferators-activated receptor-alpha (Benani, A. *et al.*, 2004).

5.26.2.3 Alterations in Receptor and Ion Channel Expression, Activity, or Cellular Location

5.26.2.3.1 Neuropeptide receptors

Recent studies show that there is an increase in the internalization of NK-1 receptors in the spinal cord dorsal horn following electrical nerve or noxious peripheral stimulation, and that this internalization is enhanced in rats with inflammatory or nerve injuries (Allen, B. J. *et al.*, 1999). There is also an upregulation of NK-1 receptors in the spinal cord dorsal horn in response to hind paw inflammation induced by CFA and following sciatic nerve transection (Aanonsen, L. M. *et al.*, 1992). Importantly, upregulation of dorsal horn NK-1 mRNA after partial sciatic nerve ligation is significantly correlated with the development of thermal hyperalgesia (Taylor, B. K. and McCarson, K. E., 2004). The importance of NK-1 receptors to the development of hyperalgesia after tissue injury is also highlighted by the finding that destruction of neurons with NK-1 receptors with the toxin saporin bound to SP abolishes the development of mechanical and thermal hyperalgesia following intraplantar capsaicin injection (Khasabov, S. G. *et al.*, 2002). NK-1 knockout mice also have attenuated dorsal horn neuronal responses to suprathreshold stimuli and a reduction of windup of deep dorsal horn neurons after C-fiber electrical nerve stimulation (Suzuki, R. *et al.*, 2003).

As for other neuropeptide receptors, it has been shown that sciatic nerve transection produces a marked increase if CCK-B receptor mRNA in the dorsal root ganglia (Zhang, X. *et al.*, 1993a). Although there is no change in the expression of the VIP/PACAP receptor PAC1, there is a decrease in VPAC1 and an increase in VPAC2 in the dorsal horn following CCI of the sciatic nerve.

5.26.2.3.2 Excitatory amino acid receptors

The NMDA receptor has two subunits NMDAR1 (NR1) and NMDAR2 (NR2), with four splice variants of the NR2 subunit (NR2A–D). Two of the NR2 subunits are heavily expressed in the spinal cord dorsal horn and have been studied in respect to plasticity associated with nociception. Recent evidence indicates that there is enhanced phosphorylation of the NR1 subunit of rat dorsal horn neurons after intradermal injection of capsaicin (Zou, X. *et al.*, 2000) or after noxious heat stimulation of the hind paw (Brenner, G. J., *et al.*, 2004), effects which depends on the activation of kinases, including PKA and/or PKC. Elevated levels of phosphorylated NR1 is also found in the spinal dorsal horn of rats with an excitotoxic injury of the spinal cord that causes central neuropathic pain (Caudle, R. M. *et al.*, 2003), or following hind paw inflammation with carrageenan (Caudle, R. M. *et al.*, 2005).

There is also a prolonged increase in the phosphorylation of NR2B subunits in rat spinal dorsal horn after inflammation induced by hind paw injection of CFA, that is dependent on activation of PKC and Src kinase (Guo, W. *et al.*, 2002), although decreases in rat spinal NR2B phosphorylation have also been observed after hind paw inflammation (Caudle, R. M. *et al.*, 2005). Increased phosphorylation of NR2B in spinal dorsal horn has also been observed in mice with transected sciatic nerves. The increased phosphorylated NR2B was attenuated by administration of a NR2B selective antagonist and in mice lacking Fyn kinase, a Src-family kinase (Abe, T. *et al.*, 2005). Recently, the C-fiber-stimulated windup of spinal dorsal horn

neurons was shown to be attenuated by i.v. administration of a selective NR2B antagonist (Kovacs, G. *et al.*, 2004). The importance of phosphorylation of spinal NR subunits to central sensitization is based on now long established evidence that such phosphorylation produces an enhancement of Ca^{2+} currents at NMDA receptor channels (Chen, L. and Huang, L.-Y. M., 1992). Thus, PKC activation, initiated by glutamate- or aspartate-induced PLC activity and Ca^{2+} influx through NMDA channels, leads to further influx of Ca^{2+} through NMDA channels, creating a positive feedback loop for glutamate and aspartate neurotransmission. As described above, a similar mechanism has been demonstrated for pathways that involve Src or Fyn kinase (Yu, X. M. *et al.*, 1997; Tezuka, T. *et al.*, 1999).

A recent question concerning synaptic activity at glutamate synapses is the issue of possible alterations in the trafficking of glutamate receptor to the plasma membrane and synapses of postsynaptic neurons. In recent years it has been established that glutamate receptors move between the cell cytoplasm and the plasma membrane, altering the number of receptors that are available to respond to glutamate and aspartate. Generally referred to as receptor trafficking, glutamate receptors are inserted into and removed from the plasma membrane by exocytosis and endocytosis (or internalization), respectively, and diffused laterally within the plasma membrane (Collingridge, G. L. *et al.*, 2004). Recent studies have implicated trafficking of AMPA (Malinow, R. R., and Malenka, R. C., 2002), kainite (Jaskolski, F. *et al.*, 2005), and NMDA (Carroll, R. C. and Zukin, R. S., 2002) receptors as key processes in regulating synaptic plasticity.

Alterations in the activity of AMPA receptors are implicated in plasticity associated with nociception. AMPA receptors in lamina III–IV of the dorsal horn are upregulated following dorsal rhizotomy (Carlton, S. M. *et al.*, 1998). There are four subunits of AMPA receptors, known as GluR1–4, some of which have splice variants, and GluR1 and GluR2 are predominant in the spinal cord (Nagy, G. G. *et al.*, 2004). It has recently been shown that there is a PKA- and PKC-dependent upregulation of phosphorylated GluR1 in the spinal cord dorsal horn of rats that have received a hind paw injection of capsaicin or noxious stimulation (Fang, L. *et al.*, 2003; Nagy, G. G. *et al.*, 2004). Recent evidence also indicates that GluR1 receptors are trafficked to the plasma membrane of dorsal horn neurons in response to visceral inflammation (Galan, A. *et al.*, 2004), via a CaMK-II-dependent mechanism. This raises the possibility that noxious stimulation may lead to a recruitment of functional AMPA receptors to the postsynaptic membrane and synapses of spinal neurons that normally do not have functional AMPA receptors. The phenomenom of silent synapses has been demonstrated in cultured hippocampal neurons exposed to stimuli that produce LTP (Liao, D. *et al.*, 1995), and may contribute to hyperexcitability of dorsal horn neurons in persistent pain conditions (Kerchner, G. A. *et al.*, 1999).

Recent studies have demonstrated alterations in the expression of various mGluRs in the DRG and dorsal horn of rats following nerve injury or persistent pain. There is a dramatic downregulation of mGluR1 mRNA in rat L5 DRG cells following tibial nerve axotomy (Hofmann, H. A. *et al.*, 2001). In contrast, mGluR5 immunoreactivity is increased in L4 and L5 DRGs of rats with L5 SNL (Hudson, L. J. *et al.*, 2002), and in the rat spinal cord dorsal horn after hind paw carrageenan injection (Dolan, S. *et al.*, 2003). There is also increased mGluR3 mRNA in the dorsal horn of rats with their hind paws exposed to ultraviolet irradiation (Boxall, S. J. *et al.*, 1998), and an upregulation of both mGluR3 and mGluR5 mRNA in the dorsal horn of sheep with chronic hindlimb inflammation (Dolan, S. *et al.*, 2003). Upregulations of mGluR2, 3, and 5 mRNA in the dorsal horn have also been reported a sheep model of postsurgical pain (Dolan, S. *et al.*, 2004). Spinal mGluR1, but not mGluR5, mRNA is also upregulated in response to spinal cord injury, while group II mGluRs are downregulated (Mills, C. D. *et al.*, 2001).

5.26.2.3.3 Other receptors

In addition to effects on neuropeptides and EAA receptors, inflammatory and nerve injuries that produce hyperalgesia are known to produce alterations in various other transmitter receptors and ion channels in neurons in spinal cord dorsal horn or DRG neurons. Sciatic nerve transection produces an upregulation of GABA-A and a downregulation of GABA-B receptors in the rat spinal cord dorsal horn (Castro-Lopes, J. M. *et al.*, 1995). A similar downregulation of GABA-B receptors occurs after joint inflammation induced by CFA injection in the rat knee, but no change in GABA-A receptors was found (Castro-Lopes, J. M. *et al.*, 1995). There is also a downregulation of μ-opioid receptor immunoreactivity in the rat and monkey spinal cord dorsal horn following peripheral nerve axotomy (Zhang, X. *et al.*, 1998). In addition, there is an increase in phosphorylated μ-opioid receptors following sciatic nerve ligation (Narita, M. *et al.*, 2004). The reduction in

number of μ-opioid receptors or the phosphorylation of remaining receptors may explain why morphine-induced antinociception (Ossipov, M. H. *et al.*, 1995; Narita, M. *et al.*, 2004) and the presynaptic inhibitory effects of μ-opioids (Kohno, T. *et al.*, 2005) are reduced in mice and rats with peripheral nerve injury, although see also Suzuki R. *et al.* (1999). There is, however, also an increase in the levels of phosphorylated κ-opioid receptors in the spinal cord dorsal horn of mice with a partial sciatic nerve lesion, an effect that is not shown in prodynorphin knockout mice that have enhanced tactile allodynia and thermal hyperalgesia (Xu, M. *et al.*, 2004). These findings suggest that the loss of endogenous dynorphin activity at κ-opioid receptors may also contribute to allodynia and hyperalgesia after nerve injury.

In contrast to the effects of opioid receptors, CCI of the sciatic nerve leads to a MAPK-dependent upregulation of spinal cannabinoid-1 (CB-1) receptors (Lim, G. *et al.*, 2003). The upregulation of spinal CB-1 was determined to be responsible for the anti-allodynic and antihyperalgesic effects of a CB-1 agonist in CCI rats, as the reduction in mechanical allodynia and thermal allodynia produced by Win 55,212-2 was lost in rats pretreated with an ERK inhibitor (PD98059) that blocked the spinal CB-1 upregulation (Lim, G. *et al.*, 2003). CCI of the rat sciatic nerve also leads to an upregulation of P2X3 receptors in spinal cord dorsal horn (Novakovic, S. D. *et al.*, 1999). This upregulation may contribute to hyperalgesia and allodynia, as an adenosine kinase inhibitor produces a greater inhibition of post-discharge, windup, and C-fiber-evoked responses in spinal cord neurons of rat with SNLs than in sham controls. Recent studies also indicate that there is an upregulation of $\alpha 3$ and $\alpha 5$ spinal nicotinic acetylcholine (nAcH) receptors following rat SNL (Vincler, M. and Eisenach, J. C., 2004), and an increase in spinal melanocortin (MC) receptors after CCI of the rat sciatic nerve (Vrinten, D. H. *et al.*, 2000). It is expected that upregulated $\alpha 5$ nAcH and MC receptors may contribute to allodynia after nerve injuries, as an $\alpha 5$ nAcH antisense olgionucleotides and an MC receptor antagonist significantly attenuate mechanical allodynia in SNL and CCI rats, respectively (Vrinten, D. H. *et al.*, 2000; Vincler, M. A. and Eisenach, J. C., 2005).

5.26.2.3.4 Scaffolding and adaptor proteins

NMDA receptors bind directly to membrane-associated guanylate kinases (MAGUKs) that regulate surface and synaptic NMDAR trafficking in the CNS (Ponting, C. P. *et al.*, 1997). MAGUKs include the adaptor proteins known as postsynaptic density proteins 93 and 95 (PSD-93, PSD-95), which are abundantly expressed in the spinal cord dorsal horn (Garry, E. M. *et al.* 2003; Tao, Y. X. *et al.*, 2003). Knockout of PSD-93 reduces surface NR2A and NR2B, lowers NMDA receptor-mediated postsynaptic currents and potentials, and reduces hyperalgesia and/or allodynia in mice with SNL or hind paw injection of CFA (Tao, Y. X. *et al.*, 2003). Antisense knockdown of spinal cord PSD-93 also reduces mechanical allodynia and thermal hyperalgesia in rats with hind paw CFA injection or following peripheral nerve injury (Zhang, B. *et al.*, 2003). Knockout or knockdown of PSD-95 also reduces hyperalgesia and allodynia in CCI mice or in rats with L5 SNL, respectively (Tao, F. *et al.*, 2001; Garry, E. M. *et al.*, 2003).

Homer is an intracellular scaffolding protein that is implicated in the intracellular retention and trafficking of group I mGluRs (Roche, K. W. *et al.*, 1999; Ango, F. *et al.*, 2000). Homer proteins also interact with the postsynaptic density protein Shank, a PDZ domain-containing protein binding to the PSD-95/NMDA receptor complex (Naisbitt, S. *et al.*, 1999; Tu, J. C. *et al.*, 1999). There are increases in the levels of both Homer and Shank in spinal cord dorsal horn in rats with CCI of the sciatic nerve at the time points when they exhibit mechanical allodynia and thermal hyperalgesia (Miletic, G. *et al.*, 2005). Another scaffolding protein, neurofilament light chain (NFL) protein, is downregulated in the DRG and spinal dorsal horn of rats with inflammation after a hind paw injection of zymosan (Kunz, S. *et al.*, 2004), the breakdown of NFL protein and inflammatory hyperalgesia were blocked with an inhibitor of the protease calpain. The cell adhesion molecule E-cadherin is dramatically downregulated in spinal cord dorsal horn in response to sciatic nerve transection (Brock, J. H. *et al.*, 2004), while the microtubule associated protein 1B is upregulated (Soares, S. *et al.*, 2002). The presynaptic vesicle protein synaptophysin is increased in spinal dorsal horn in parallel with thermal hyperalgesia in CCI rats (Chou, A. K. *et al.*, 2002).

5.26.2.3.5 Ion channels

Inflammatory and nerve injuries lead to alterations in sensory neuron ion channel expression, distribution and function that contribute to hyperalgesia and allodynia. In particular, evidence indicates that various sodium (Na^+) channels subtypes are altered in

association with inflammation or neuropathy. There is an upregulation of the Na^+ channel subunit $Na_V1.3$ in DRG neurons or spinal cord dorsal horn neurons following peripheral nerve axotomy (Waxman, S. G. *et al.*, 1994), traumatic spinal cord injury (Hains, B. C. *et al.*, 2003) and CCI of the sciatic nerve (Hains, B. C. *et al.*, 2004), as well as hind paw injection of carrageenan (Black, J. A. *et al.*, 2004). In the case of CCI, a spinal upregulation likely contributes to hyperalgesia/allodynia, as i.t. administration of antisense oligonucleotides to $Na_V1.3$ decreased expression to normal levels and decreased the enhanced spontaneous activity and evoked responses of dorsal horn neurons, as well as reducing thermal hyperalgesia and mechanical allodynia in CCI rats (Hains, B. C. *et al.*, 2004).

There is also an upregulation of Na_V 1.7 and $Na_V1.8$, but not $Na_V1.9$, in DRG in response to hind paw injection of carrageenan (Tanaka, M. *et al.*, 1998; Black, J. A. *et al.*, 2004). Hyperalgesia in response to hind paw inflammation is reduced or delayed in rats treated with $Na_V1.8$ antisense oligonucleotides (Khasar, S. G. *et al.*, 1998) or in $Na_V1.8$ knockout mice (Akopian, A. N. *et al.*, 1999). Although $Na_V1.8$ channels are not upregulated in DRG after nerve injury (Okuse, K. *et al.*, 1997; Novakovic, S. D. *et al.*, 1998), antisense oligonucleotide knockdown of $Na_V1.8$ attenuates neuropathic pain in rats with SNL (Lai, J. *et al.*, 2002; Gold, M. S. *et al.*, 2003). The effectiveness of the knockdown may be explained by findings that there is a redistribution of $Na_V1.8$ channels in injured nerves with an accumulation of these channels at the site of the nerve injury (Novakovic, S. D. *et al.*, 1998; Gold, M. S. *et al*, 2003).

As for $Na_V1.9$, it has been shown that knockdown of its protein has no influence on allodynia or hyperalgesia in SNL rats (Porreca, F. *et al.*, 1999), while disruption of the SCN11A gene, which encodes $Na_V1.9$, attenuates thermal hyperalgesia and spontaneous pain after peripheral inflammation (Priest, B. T. *et al.*, 2005).

Ca^{2+} channels also show changes in expression following nerve injury. Thus, after axotomy or partial nerve ligation of the sciatic nerve there is an upregulation of $Ca_V1.2$ (L-type α1C) and $Ca_V2.3$ (R-type α1E) (Yang, L. *et al.*, 2004; Dobremez, E. *et al.*, 2005). Evidence suggests that L-type Ca^{2+} channels contribute to tonic nociception (Del Pozo, E. *et al.*, 1987; Coderre, T. J. and Melzack, R., 1992b), and recent evidence indicates that $Ca_V2.3$ knockout mice have reduced responses to inflammatory pain (Saegusa, H. *et al.*, 2000), suggesting that R-type Ca^{2+} channels may also play a role in hyperalgesia/allodynia. There is also an upregulation of $Ca_V2.2$ (N-type Ca^{2+} channels α1B) in both DRG and spinal dorsal horn after hind paw injection of carrageenan (Yokoyama, K. *et al.*, 2003) or CCI of the sciatic nerve (Cizkova, D. *et al.*, 2002b). Many preclinical studies have shown that antagonists of N-type Ca^{2+} channels reduce allodynia or hyperalgesia associated with inflammatory or nerve injuries, and suggest that $Ca_V2.2$ is a key target (see Winquist, R. J. *et al.*, 2005 for a review). There is also a reduction of tactile allodynia and thermal hyperalgesia associated with SNL in $Ca_V2.2$ knockout mice (Saegusa, H. *et al.*, 2001). Although the P-type Ca^{2+} channel have also been implicated in the development of hyperalgesia, the effects of their antagonists have been less effective (Sluka, K. A., 1998; Matthews, E. A. and Dickenson, A. H., 2001), and a selective Q-type antagonist was ineffective (Nebe, J. *et al.*, 1997). In addition, others have found in response to axotomy or CCI of the sciatic nerve there is a downregulation of $Ca_V1.2$ (L-type α1C), $Ca_V1.3$ (L-type α1D), $Ca_V3.2$ (T-type α1H) and $Ca_V3.3$ (T-type α1I) mRNA expression in rat DRG (Kim, D. S. *et al.*, 2001). A role for T-type channels in hyperalgesia is suggested since antisense knockdown of $Ca_V3.2$ reduces both hyperalgesia and allodynia in rats with CCI of the sciatic nerve (Bourinet, E. *et al.*, 2004).

Recent studies also show there is an upregulation of $\alpha_2\delta$ Ca^{2+} channel auxillary subunits found in the DRG and spinal dorsal horn of rats after SNL and to a lesser extent CCI of the sciatic nerve (Luo, Z. D. *et al.*, 2001; 2002). The upregulation of $\alpha_2\delta$ subunits is temporally related to the development of tactile allodynia after SNL, and i.t. treatment of antisense oligonucleotide to $\alpha_2\delta$ diminishes the tactile allodynia in SNL rats (Li, C. Y. *et al.*, 2004). The importance of this subunit to hyperalgesia and allodynia is also highlighted by the fact that the $\alpha_2\delta$ subunit is the only known binding site for gabapentin and pregabalin which are effective antihyperalgesic agents for many neuropathic pain patients (Frampton, J. E. and Foster, R. H., 2005; Wiffen, P. J. *et al.*, 2005).

There is considerable evidence that sensory neuron vanilloid receptors, including TRPV1 (VR-1) and TRPV2 (VRL-1), play a critical role in the transduction of noxious heat (Caterina, M. J. and Julius, D., 2001). An up-regulation of TRPV1 has also been found in the spared L4 DRG following L5 SNL (Hudson, L. J. *et al.*, 2001) and CCI (Wilson-Gerwing, T. D. *et al.*, 2005). Importantly, the upregulation of L4 DRG TRPV1 correlates

temporally with the development and maintenance of thermal hyperalgesia after L5 SNL (Fukuoka, T. *et al*., 2002). I.t. administration of NT-3 reduces thermal hyperalgesia as well as reducing the elevated DRG TRPV1 expression in CCI rats (Wilson-Gerwing, T. D. *et al*., 2005). Systemic treatment with a TRPV1 antagonist reduces thermal hyperalgesia induced by hindpaw capsaicin, carrageenan or CFA, as well as mechanical hyperalgesia after partial sciatic nerve lesion in the guinea pig (Walker, K. M. *et al*., 2003), and carrageenan-induced thermal hyperalgesia is absent in TRPV1 knock-out mice (Davis, J. B. *et al*., 2000). In contrast, i.t. administration of a TRPV1 antagonist is less effective at reducing noxious stimulus-evoked dorsal horn neuronal responses in SNL rats as compared to sham controls (Kelly, S. and Chapman, V., 2002). Evidence suggests that there is also an up-regulation of TRPV1 in DRG associated with peripheral inflammation, and that the upregulation is associated with thermal hyperalgesia and depends on p38 MAPK activation (Ji, R. R. *et al*., 2002b). Recent evidence indicates that while the levels of TRPV2 receptors in DRG are not affected by peripheral nerve axotomy, their levels in sympathetic post-ganglionic neurons are upregulated after nerve sections (Gaudet, A. D. *et al*., 2004).

5.26.2.4 Alterations in Transporter Activity

5.26.2.4.1 Glutamate transporters

Glutamate transporters are critical for the reuptake of transmitter in glutamate synapses, and the major ones include vesicular glutamate transporters VGluT1-3 and EAAC1 and glial glutamate transporters (GLAST and GLT-1) (Shigeri, Y. *et al*., 2004). There is a downregulation of EAAC1, GLAST, and GLT-1 is the spinal cord dorsal horn of CCI rats at time points when they exhibit mechanical allodynia and thermal hyperalgesia (Sung, B. *et al*., 2003). The EAAC1, GLAST, and GLT-1 downregulation in rats with taxol-induced neuropathy is paralleled by increases in spontaneous activity, prolonged afterdischarges, and windup in dorsal horn neurons (Cata, J. P. *et al*., 2005; Weng, H. R. *et al*., 2005). Dorsal horn EAAC1, GLAST, and GLT-1 are also all downregulated in chronic morphine-treated rats in a manner that is temporally correlated with the development of thermal hyperalgesia (Mao, J. *et al*., 2002a; Lim, G. *et al*., 2005). I.t. administration of inhibitors of glutamate transporters has also been shown to produce mechanical allodynia and thermal hyperalgesia (Mao, J. *et al*., 2002a; Liaw, W. J. *et al*., 2005). Finally, using *in vivo* voltametry and pressure-ejected glutamate, it has been shown that the uptake of glutamate is significantly reduced in the spinal cord dorsal horn of rats with SNL (Binns, B. C. *et al*., 2005), illustrating the impact of glutamate transporter suppression.

5.26.2.4.2 Cation chloride transporters

Recent studies suggest that alterations in the function of cation chloride cotransporters may play a role in hyperalgesia states by modulating the chloride concentration inside nociceptive cells. Galan A. and Cervero F. (2005) report that there is a 50% increase in the Na^+–Cl^-–K^+ isoform 1 (NKCC1) in the dorsal horn of mice after intracolonic capsaicin injection, as well as an increase in the phosphorylation of NKCC1. In addition, NKCC1 knockout mice have a reduction in mechanical allodynia to stroking induced by intradermal capsaicin (Laird, J. M. *et al*., 2004). They propose that increased NKCC-1 shifts the anion gradient and alters normal presynaptic inhibition in dorsal horn by producing an increase in the intracellular concentration of chloride and an enhanced GABA-mediated primary afferent depolarization that leads to mechanical allodynia (Galan, A. and Cervero, F., 2005). Thus, GABAergic depolarization in primary afferents will lead to a cross excitation between low- and high-threshold afferents that produce allodynia by reducing GABA-mediated presynaptic inhibition (Price, T. J. *et al*., 2005).

Furthermore, Coull J. A. *et al*. (2003) found a reduction in the potassium chloride exporter (KCC2) in the spinal dorsal horn of CCI rats. This decrease was paralleled by a shift in the transmembrane anion gradient that caused normally inhibitory anion synaptic currents to be excitatory, and an increase in the net excitability of lamina I dorsal horn neurons in CCI rats (Coull, J. A. *et al*., 2003). In addition, blockade or knockdown of spinal KCC2 in intact rats produced mechanical allodynia, suggesting that disruption of anion homeostatis could be responsible for allodynia in neuropathic rats (Coull, J. A. *et al*., 2003). The decrease in spinal KCC2 is proposed then to result in a loss of GABA-/glycinergic inhibitory tone and, in some cases, inverting its action into net excitation that causes allodynia after nerve injury (Price, T. J. *et al*., 2005).

5.26.2.5 Glial Cell Alterations

5.26.2.5.1 Microglia

Activation of microglial and the release of proinflammatory cytokines from these cells was originally

found to play a significant role in illness-induced hyperalgesia, including that produced by bacterial endotoxins and viruses such as HIV-1 (see Watkins, L. R. and Maier, S. F., 1999 for a review). There is also an increase in activated microglia, as indicated by increased complement receptor C3bi (OX-42) immunoreactivity in rat spinal cord dorsal horn following sciatic nerve transection (Eriksson, N. P. *et al.*, 1993). There is an increase in immunoreactivity for microglial markers OX-42 and histocompatibility complex II (OX-6), as well, in the dorsal horn of rats with partial sciatic nerve ligation (Coyle, D. E., 1998), with a linear correlation between increased mechanical allodynia and increased OX-42 staining. OX-42 is also increased in dorsal horn following injury of spinal nerve roots, and is accompanied by increases in expression of the interleukin 1β (IL-1β) (Hashizume, H. *et al.*, 2000) and the fractalkine receptor X3CR1 in dorsal horn microglia (Verge, G. M. *et al.*, 2004; Lindia, J. A. *et al.*, 2005). Peripheral inflammation induced by hind paw CFA injections also leads to increases in microglial markers, including OX-42, Mac-1, TLR4, and CD14 in spinal dorsal horn (Raghavendra, V. *et al.*, 2004). I.t. administration of an inhibitor of microglial cell activation attenuates mechanical allodynia in rats with sciatic nerve inflammation, as well as reducing the expression of the proinflammatory cytokines IL-1β and tumor necrosis factor alpha (TNFα) and their converting enzymes in spinal dorsal horn after sciatic nerve inflammation (Milligan, E. D. *et al.*, 2003; Ledeboer, A. *et al.*, 2005). A glial metabolic inhibitor also reduces C-fiber afferent-stimulated LTP in spinal cord dorsal horn neurons (Ikeda, H. and Murase, K., 2004).

Mechanical allodynia in ipsilateral and contralateral hind paws of rats with a unilateral inflammation of the sciatic nerve is also reduced following i.t. treatment with antagonists of the proinflammatory cytokines IL-1β, IL-6, and TNFα (Milligan, E. D. *et al.*, 2003). I.t. administration of the cytokine fractalkine produces mechanical allodynia and thermal hyperalgesia that is blocked by an inhibitor of microglial activation, as well as an antagonist of IL-1 and antibodies to IL-6 (Milligan, E. D. *et al.*, 2004; 2005). In contrast, a neutralizing antibody of the fractalkine receptor (CX3CR1) delays the development of mechanical allodynia and thermal hyperalgesia in rats with CCI or inflammatory injury of the sciatic nerve (Milligan, E. D. *et al.*, 2004). Increased cytokine activity in spinal nerve injured rats leads to a phosphorylation of p38 MAPK in dorsal horn microglia, and a p38 MAPK inhibitor reduces mechanical allodynia in neuropathic rats (Inoue, K. *et al.*, 2003; Tsuda, M. *et al.*, 2004). The expression of the P2X4 receptor, a subtype of ATP receptors, is also enhanced in rat spinal microglia after SNL, and ATP acting at P2X4 receptor on microglia leads to the release of cytokines which activate p38 MAPK (Inoue, K., 2006). Pharmacological blockade or knockdown of P2X4 receptors reverse mechanical allodynia after SNL in rats, while i.t. administration of microglia activated by P2X4 receptor stimulation produces mechanical allodynia in naïve rats (Tsuda, M. *et al.*, 2003).

5.26.2.5.2 Astrocytes

There is also an increase in activated astrocytes as indicated by increased staining of glial fibrillary acidic protein (GFAP) in rat spinal cord dorsal horn following sciatic nerve transection (Eriksson, N. P. *et al.*, 1993) or partial sciatic nerve ligation (Ma, W. and Quirion, R., 2002). The degree of thermal hyperalgesia or mechanical allodynia in rats with CCI of the sciatic nerve (Garrison, C. J. *et al.*, 1991) and injury of spinal nerve roots (Hashizume, H. *et al.*, 2000) or partial sciatic nerve injury (Coyle, D. E., 1998), respectively, is correlated with the magnitude of GFAP staining in the spinal cord dorsal horn. GFAP is also increased in dorsal horn following SNL, and is accompanied by increases expression the cytokine fibroblast growth factor-2 (Madiai, F. *et al.*, 2003) and increases in fractalkine (CX3CL1) in astrocytes (Lindia, J. A. *et al.*, 2005). Hind paw injection of CFA also produces spinal astrocyte activation as indicated by increased GFAP and S100B expression in the dorsal horn (Raghavendra, V. *et al.*, 2004). There is also an increase in MAPK activity in astrocytes as indicated by increases in phosphorylated ERK and JNK in cells that colocalize GFAP (Ma, W. and Quirion, R., 2002).

5.26.2.5.3 Neuron–glial interactions

Many of the factors released by glial cells discussed in the two above sections (particularly cytokines) act to sensitize neurons and represent neuron–glial interactions that contribute to hyperalgesia and/or allodynia. A recent study by Coull J. A. *et al.* (2005) provides an excellent example of a neuronal–glial interactive pathway that has been implicated in the development of allodynia and hyperalgesia in nerve-injured rats. These authors have shown that ATP-stimulated microglia cause a shift in the anion reversal potential in spinal lamina I neurons similar to that observe in rats with sciatic nerve injury. The

shift inverts the polarity of GABA currents so that GABA produces excitation rather than the normal inhibition of lamina I neurons. In addition, they showed that applying BDNF mimics the alteration in anion gradient, that ATP stimulation evokes the release of BDNF from microglia, and that blocking BDNF effects on TrkB receptors reverses allodynia and anion gradient shifts that follow nerve injury or administration of ATP-stimulated microglia (Coull, J. A. *et al.*, 2005). This study illustrates the importance of neuron–glial interactions to allodynia in neuropathic rats, and indicates that BDNF is a crucial signalling molecule between microglia and neurons.

5.26.2.6 Descending Facilitation

Sensitization of spinal cord dorsal horn neurons is not only enabled by increased input from primary afferent nociceptors, but also by a decrease in descending inhibitory controls and a phenomenon known as descending facilitation. The role of descending facilitation was reported by Watkins L. R. *et al.* (1994b) who found lesions of the NRM reduced illness-induced hyperalgesia. Pertovaara, A. (1998) further reported that mustard oil application to the rat hind paw produced a facilitation of evoked nociceptive responses of dorsal horn neurons that was attenuated by spinal transection or lidocaine block of the rostroventromedulla (RVM). Descending facilitation of spinal neurons has also been observed through a pathway that involves the nucleus reticularis gigantocellularis (Zhuo, M. and Gebhart, G. F. 1992). Spinal cord transection or RVM blocks, as well as inhibition of RVM NMDA receptors or NO synthase, also prevent the development of secondary hyperalgesia in rats after topical mustard oil, carrageenan inflammation and SNL (see Urban, M. O. and Gebhart, G. F., 1999). Mechanical allodynia after SNL in rats is reversed by ipsilateral dorsal column lesions of by administration of lidocaine into the ipsilateral nucleus gracilis, suggesting that descending facilitation from supraspinal sites depends on afferent signals transmitted by large myelinated fibers in the dorsal column pathway (Sun, H. *et al.*, 2001). Importantly, large myelinated fibers projecting to the nucleus gracilis have been found to change their phenotype and express SP following sciatic nerve transection, and NK-1 receptor antagonists suppress stimulus-induced Fos expression in the gracile nucleus in sciatic nerve lesioned rats (Noguchi, K. *et al.*, 1995). It has also been suggested that a descending facilitatory serotonergic pathway is activated by superficial dorsal horn neurons that express NK-1 (Suzuki, R. *et al.*, 2002).

5.26.2.7 Anatomical Changes

5.26.2.7.1 Cell death and apoptotic genes

5.26.2.7.1.(i) Cell death Transection of the sciatic nerve results in transganglionic degeneration atrophy and signs of Wallerian degeneration in the monkey spinal cord (Knyihar-Csillik, E. *et al.*, 1987). In rats, there is a dramatic increase of terminal deoxynucleotidyl transferase-mediated biotinylated UTP nick end labeling (TUNEL)-stained interneurons in superficial (Azkue, J. J. *et al.*, 1998) and deep (Oliveira, A. L. *et al.*, 1997) dorsal horn neurons after sciatic nerve transection, indicating that apoptotic mechanisms are involved in the cell death process. CCI of the rat sciatic nerve also leads to degenerative changes in spinal cord with the appearance of hyperchromatic or dark neurons (Sugimoto, T. *et al.*, 1990; Nachemson, A. K. and Bennett, G. J., 1993) and TUNEL-labeled neurons (Whiteside, G. T. and Munglani, R., 2001; Maione, S. *et al.*, 2002) in the dorsal horn. The apoptotic degeneration after nerve injury appears to depend on EAA-induced excitotoxicity since premptive treatment with NMDA or mGluR5 antagonists reduces TUNEL staining after transection (Azkue, J. J. *et al.*, 1998) or CCI (Whiteside, G. T. and Munglani, R., 2001; de Novellis, V. *et al.*, 2004) of the sciatic nerve. Reducing neuronal apopotosis in spinal dorsal horn by administration of erythroprotein also prevents mechanical allodynia in rats with spinal nerve root crush injury (Sekiguchi, Y. *et al.*, 2003).

Recent evidence suggest that there is a decrease in GABA-A-mediated inhibitory postsynaptic potentials (IPSPs) in rats with spared nerve injury or CCI (Moore, K. A. *et al.*, 2002), suggesting a reduction in the presynaptic release of GABA after nerve injury. Partial nerve injured was also found to produce a reduction in the GABA synthesizing enzyme glutamic acid decarboxylase (GAD) as well as increased TUNEL staining indicative of apoptosis in dorsal horn (Moore, K. A. *et al.*, 2002), although it has been recently suggested that most TUNEL staining is in microglia and not neurons (Polgar, E. *et al.*, 2005). Blocking apoptosis with a caspase inhibitor prevents the loss of spinal GABAergic interneurons, the reduction in spinal IPSCs, and mechanical and cold allodynia after CCI or partial sciatic nerve injury (Scholz, J. *et al.*, 2005). Furthermore, rats with SNL

have alterations in the normal inhibition of C-fiber-evoked activity by GABA-A agonists (Kontinen, V. K. and Dickenson, A. H., 2000; Sokal, D. M. and Chapman, V., 2003), and spinal cord injured rats with allodynia do not exhibit the normal increases in evoked responses of dorsal horn neurons after ionotophorectic application of GABA-A antagonists (Drew, G. M. *et al.*, 2004). In addition, a reduction in the glycinergic inhibitory control of spinal neurons occurs after CFA-induced inflammation of the hind paw as reflected by a reduced mean frequency of glycine-mediated miniature IPSCs in lamina I neurons (Muller, F. *et al.*, 2003). All these findings point to a potentially important contribution to hyperalgesia and/or allodynia of cell death of inhibitory neurons.

5.26.2.7.1.(ii) Apoptotic genes Recent research suggests that chronic pain produces alterations in apoptotic and antiapoptotic genes either following gene transcription or by posttranslational mechanisms. CCI of the sciatic nerve leads to alterations of dorsal horn levels of various members of Bcl-2 gene family, including an upregulation of the proapoptotic gene Bax and the antiapoptotic genes Bcl-2 and Bcl-xL, and a downregulation of Bcl-xS (Maione, S. *et al.*, 2002; de Novellis, V. *et al.*, 2004). Importantly, spinal neuron apoptosis indicated by TUNEL staining, thermal, and mechanical hyperalgesia and the alterations in apoptotic genes were all reversed by treatment with an mGluR5 antagonist (de Novellis, V. *et al.*, 2004). There is also an upregulation of the proapoptotic protein Bax and caspase 3, and a downregulation of the antiapopototic protein Bcl-2 in chronic morphine-treated rats that exhibit thermal hyperalgesia (Mao, J. *et al.*, 2002b). Neuronal apopotosis in dorsal horn and thermal hyperalgesia in chronic morphine-treated rats are attenuated by i.t. administration of a nonselective caspase and a caspase-3-selective inhibitor (Mao, J. *et al.*, 2002b). I.t. quisqualic acid-induced excitotoxic spinal cord injury produces pain-related behaviors and increased expression of CD-95 or Fas ligand and TNF-related apoptotis-inducing ligand (TRAIL), and i.t. treatment with IL-10, an anti-inflammatory cytokine, reduced pain-related behaviors in spinal injured rats (Plunkett, J. A. *et al.*, 2001). Furthermore, inhibition of activator (1,2,8, and 9) and effector (3) caspases attenuates neuropathic pain induced in rats by cancer and HIV/AIDS chemotherapeutic agents, as well as pain-related behavior induced by TNFα (Joseph, E. K. and Levine, J. D., 2004). A caspase inhibitor also reduces mechanical and cold allodynia in rats with partial nerve injury (Scholz, J. *et al.*, 2005), while an inhibitor of poly(ADP-ribose) synthetase, an enzyme involved in glutamate-induced neurotoxicity, reduces the expression of dark neurons and allodynia and hyperalgesia in CCI rats (Mao, J. *et al.*, 1997). Galectin-1, a member of the family of β-galactoside-binding animal lectins, has been shown to be a proapoptotic factor, and is increased in spinal cord dorsal horn after peripheral nerve transection (Imbe, H. *et al.*, 2003; McGraw, J. *et al.*, 2005). I.t. treatment with antibodies to galectin-1 attenuates the mechanical allodynia in the spared nerve injury model (Imbe, H. *et al.*, 2003).

5.26.2.7.2 Sprouting

5.26.2.7.2.(i) Sympathetic fibers Although controversial, there is long-standing evidence that alterations in sympathetic nervous system function plays a role in hyperalgesia and allodynia following nerve injury (Janig, W. *et al.*, 1996). Sympathetic activity may influence inputs to spinal cord dorsal horn following the development of abnormal connectivity between sympathetic efferent fibers and primary afferent fibers. McLachlan E. M. *et al.* (1993) showed that sympathetic axons sprout into the DRGs of rats with sciatic nerve transection and form basket-like structures around large neurons. Similar sympathetic fiber sprouting is observed after SNL (Chung, K. *et al.*, 1993) and partial ligation (Lee, B. H. *et al.*, 1998) or CCI of the sciatic nerve (Ramer, M. S. and Bisby, M. A., 1997). Mechanical and allodynia in SNL rats is abolished after sympathectomy, which eliminates most sprouting fibers (Chung, K. *et al.*, 1996). Sympathetic sprouting, mechanical allodynia, and thermal hyperalgesia after CCI depends on the occurrence of Wallerian degeneration (Ramer, M. S. *et al.*, 1997) and an upregulation of NGF (Ramer, M. S. and Bisby, M. A., 1997) in DRG neurons. There is also and upregulation of NGF and NT-3 in glial cells of the DRG in SNL rats, and antibodies to NGF, BDNF, and NT-3 reduce sympathetic sprouting in rat DRG and thermal hyperalgesia after SNL (Zhou, X. F. *et al.*, 1999b; Deng, Y. S. *et al.*, 2000). Sympathetic sprouting and mechanical allodynia after SNL are attenuated in IL-6 knockout mice, implicating cytokines as key factors contributing to these changes (Ramer, M. S. *et al.*, 1998).

5.26.2.7.2.(ii) Aβ fibers It it difficult to explain the development of allodynia in response to activity-

drive plasticity as Aβ fibers, which transmit low-threshold touch inputs generally do not terminate on spinal nociceptive neurons. Evidence generated over the past 15 years suggests, however, that allodynia may be partly explained the nerve injury-induced sprouting of the terminals of Aβ fibers into dorsal horn lamina I and IIo where they are able to contact spinal nociceptive neurons (Woolf, C. J. *et al.*, 1992; Shortland, P. and Woolf, C. J., 1993). It has been suggested that regenerating Aβ fibers exhibit collateral sprouting into superficial dorsal horn lamina after the terminal arbors of small Aδ and C fibers degenerate following peripheral nerve injury (Wilson, P. and Kitchener, P. D., 1996), a theory that is supported by evidence of similar Aβ fiber sprouting after local application of the C-fiber neurotoxin capsaicin to the sciatic nerve (Mannion, R. J. *et al.*, 1996). Aβ fiber sprouting into rat spinal lamina II has also been observed in rats with SNL or CCI of the sciatic nerve (Shortland, P. *et al.*, 1997; Nakamura, S. and Myers, R. R., 1999) or even chronic inflammation of the rat hind paw (Ma, Q. P. and Tian, L., 2002). Lekan H. A. *et al.* (1997) also found increased Aβ fibers in dorsal roots despite overall decreases in rat DRG cells after SNL. Both the sprouting of Aβ fibers into lamina II and mechanical allodynia after sciatic nerve injury are absent in mice lacking membrane-type 5 matrix metalloproteinase (Komori, K. *et al.*, 2004), and the sprouting is accompanied by *de novo* expression of SP, somatostatin, and PACAP in deeper lamina (Jongsma, H. *et al.*, 2000; Swamydas, M. *et al.*, 2004). The conclusions of these studies have been questioned, however, by evidence that after nerve injury Aδ fibers (Ma, Q. P. and Tian, L., 2001) or even C fibers (Tong, Y. G. *et al.*, 1999; Shehab, S. A. *et al.*, 2003) may begin to uptake the cholera toxin B subunit that has been used in the previous studies as a selective marker of Aβ fibers.

5.26.3 Conclusion

Hyperalgesia and allodynia are consequences of cutaneous or deep tissue and nerve injury and depend on both peripheral and central sensitization. Central sensitization relies on various alterations in both presynaptic DRG cells, interneurons and postsynaptic spinal cord dorsal horn neurons, as well as satellite cells in the dorsal horn and DRG. There are changes in the expression of receptors and ion channels, as well as alterations in their cellular location within neurons. There is evidence that changes in scaffolding proteins, kinases and phosphatases, and transporters influence the synaptic activity and anion gradients of pre- and postsynaptic neurons in the spinal cord dorsal horn. Activation of microglial and astrocytes and the release of mediators such as cytokines and neurotrophins result in neuron–glial interactions that also contribute to increased excitability in the spinal cord. Finally there is evidence of cell death, trans-synaptic degeneration, and the sprouting of sympathetic efferent fibers in DRG and A-fiber primary afferent fibers in the dorsal horn which contribute to central sensitization and the development and/or maintenance of hyperalgesia and allodynia.

Glossary

GABA Gamma aminobutyric acid; fast inhibitory neurotransmitter in the mammalian CNS.

GABA$_A$ receptor Chloride channel-coupled GABA receptor blocked by bicuculline.

glycine Fast inhibitory neurotransmitter in the spinal cord and brain stem.

gephyrin Postsynaptic protein mediating the clustering of $GABA_A$ and glycine receptors in the postsynaptic membrane.

cyclooxygenase-2 Inducible enzyme mediating the production of prostaglandin precursors.

EGFP Enhanced green fluorescent protein used, for example to label cells *in vitro* and *in vivo*.

KCC2 Potassium/chloride exporter protein, needed for central neurons to reduce their intracellular chloride concentration to physiological levels.

5.27.1 Molecular Architecture of Glycine Receptors

Glycine is the major inhibitory neurotransmitter in the spinal cord and brain stem. In addition, glycine is an obligatory co-agonist at excitatory glutamate receptors of the *N*-methyl-D-aspartate (NMDA) subtype. This chapter focuses on inhibitory (strychnine-sensitive) glycine receptors. These glycine receptors are heteropentameric chloride-permeable ion channels composed of α and β subunits (Legendre, P., 2001). Four different genes (*glra1–glra4*) encode for the glycine-binding α subunits and one gene (*glrb*) encodes for the so-called structural β subunit. α Subunits carry the glycine binding site and are capable of forming functional homomeric receptor channels. The β subunit permits postsynaptic clustering of glycine receptors through an interaction with the postsynaptic density protein gephyrin. Most glycine receptors in the adult are heteromeric receptors composed of $\alpha 1$ and β subunits. GlyR$\alpha 2$ forms homomeric receptor channels during embryonic development and in early postnatal life. In most organs GlyR$\alpha 2$ homomers are replaced by GlyR$\alpha 1/\beta$ heteromers during postnatal maturation. GlyR$\alpha 3$ is another adult glycine receptor subunit but much less abundant than GlyR$\alpha 1$. GlyR$\alpha 4$ is probably not expressed in humans because of a premature stop codon in the *GLRA4* gene.

5.27.2 Glycinergic Innervation in the Spinal Cord Dorsal Horn

Immunofluorescence studies have shown that markers of glycinergic innervation are abundant in the spinal cord dorsal horn (Todd, A. J. and Sullivan, A. C., 1990). Glycine receptors are found throughout the dorsal horn. As in other regions of the central nervous system (CNS), most glycine receptors in the adult spinal cord are $\alpha 1/\beta$ heteromeric receptor channels. However, in the superficial layers of the dorsal horn, where most nociceptive afferents terminate, glycine receptors contain GlyR$\alpha 3$ in addition to GlyR$\alpha 1$ and GlyRβ (Figure 1) (Harvey, R. J. *et al.*, 2004). The prominent

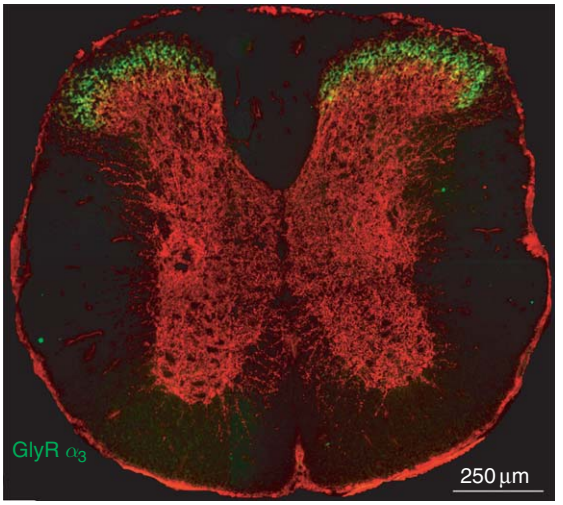

Figure 1 Expression of GlyRα3 in the spinal cord dorsal horn. GlyRα3 (green) is distinctly expressed in the superficial layers where nociceptive afferents terminate, whereas gephyrin (red), a marker for glycinergic and GABAergic synapses, is found throughout the spinal cord. Adapted from Harvey, R. J., Depner, U. B., Wässle, H., Ahmadi, S., Heindl, C., Reinold, H., Smart, T. G., Harvey, K., Schütz, B., Abo-Salem, O. M., Zimmer, A., Poisbeau, P., Welzl, H., Wolfer, D. P., Betz, H., Zeilhofer, H. U., and Müller, U. 2004. GlyR α3: an essential target for spinal inflammatory pain sensitization. Science 304, 884–887; with permission.

expression of glycine receptors in the spinal cord is accompanied by dense glycinergic innervation. Glycinergic axon terminals, characterized by the expression of the neuronal glycine transporter isoform GlyT2, and glycinergic cell bodies, identified by their immunoreactivity against glycine, are widely distributed in the dorsal horn. Recently, mice expressing enhanced green fluorescent protein (EGFP) under the transcriptional control of the GlyT2 gene have been generated (Zeilhofer, H. U. *et al.*, 2005). In the dorsal horn of these mice, numerous glycinergic (EGFP/GlyT2-positive) neurons are found in the deeper dorsal horn (laminae III–V) and in lamina I, whereas relatively few glycinergic neurons are seen in lamina II. In addition to these local inhibitory interneurons, descending antinociceptive glycinergic fiber tracts (Antal, M. *et al.*, 1996; Kato, G. *et al.*, 2006) probably contribute to the glycinergic innervation of the dorsal horn.

5.27.3 Inhibitory Glycine Receptors and Spinal Pain Control

Plenty of information meanwhile indicates that relief from synaptic inhibition by spinal blockade of glycine (and also of $GABA_A$) receptors can elicit and exaggerate nociceptive responses (for a recent review see Zeilhofer, H. U., 2005). Several groups have meanwhile demonstrated that relief from inhibition also occurs endogenously during inflammation and possibly also after peripheral nerve injury.

5.27.3.1 Glycine Receptors in the Spinal Control of Inflammatory Pain

Inflammatory pain originates to a large extent from prostaglandins, which are produced in response to inflammation and tissue damage mainly by inducible cyclooxygenase-2 (COX-2). The pivotal role of prostaglandins for pain sensitization is obvious from our everyday experience that profound analgesia can be achieved through inhibition of prostanoid formation either by the classical nonspecific cyclooxygenase (COX) inhibitors (aspirin and related drugs) or by the more recently developed COX-2-specific inhibitors (Brune, K. and Zeilhofer, H. U., 2005).

For a long time it was widely believed that prostaglandins sensitize the nociceptive system only at the level of the peripheral nociceptor. This long-held view has changed significantly since the mid-1990s when several groups demonstrated that inflammation induces COX-2 expression not only in the peripheral inflamed tissue, but also in the CNS, in particular in the spinal cord dorsal horn. A central action of prostaglandins and accordingly also a central mode of action for the analgesic action of COX inhibitors are meanwhile generally accepted (Malmberg, A. B. and Yaksh, T. L., 1992; Samad, T. A. *et al.*, 2002).

Electrophysiological experiments have shown that PGE_2 reduces inhibitory glycinergic neurotransmission in the spinal cord dorsal horn, but does not interfere with GABAergic or glutamatergic neurotransmission (Figure 2) (Ahmadi, S. *et al.*, 2002). This inhibition is (at least in adult animals) specific for neurons in the superficial layers of the dorsal horn and for PGE_2 (PGD_2, PGI_2, and $PGF_{2\alpha}$ are without effect). It involves activation of postsynaptic prostaglandin E receptors of the EP2 subtype and a specific protein kinase A (PKA)-dependent phosphorylation of GlyRα3-containing receptors, which are in the spinal cord distinctly expressed in the superficial layers (Harvey, R. J. *et al.*, 2004). Subsequent experiments using site-directed mutagenesis have shown that GlyRα3 is phosphorylated at serine 346 in the long intracellular loop between transmembrane regions 3 and 4. Figure 3 shows a schematic

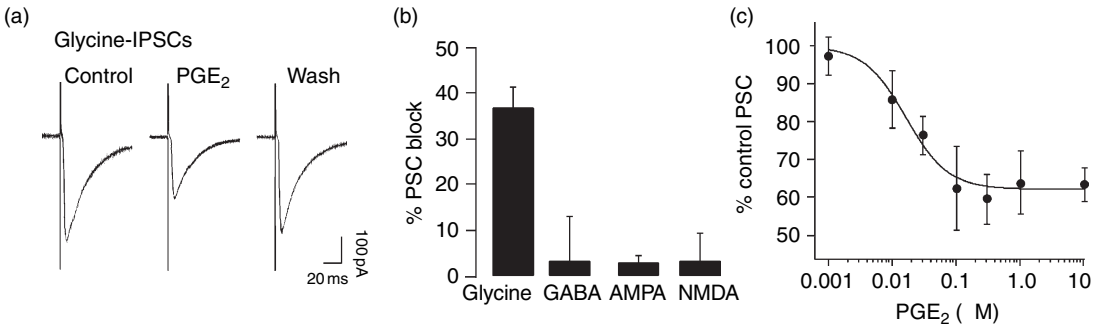

Figure 2 PGE_2 selectively inhibits glycinergic neurotransmission onto spinal cord dorsal horn neurons. (a) Averaged inhibitory postsynaptic current (IPSC) traces recorded from a neuron in the superficial dorsal horn under control conditions, in the presence of PGE_2, and after its removal. (b) Statistical analysis (mean ± SEM). Significant inhibition by PGE_2 occurred only for glycinergic IPSCs, GABAergic IPSCs, and excitatory postsynaptic currents mediated by glutamate receptors of the alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) or *N*-methyl-D-aspartate (NMDA) type remained unchanged. (c) Concentration–response curve. Significant inhibition of glycinergic IPSC occurred at low nanomolar concentrations. Adapted from Ahmadi, S., Lippross, S., Neuhuber, W. L., and Zeilhofer, H. U. 2002. PGE_2 selectively blocks inhibitory glycinergic neurotransmission onto rat superficial dorsal horn neurons. Nat. Neurosci. 5, 34–40, with permission from Nature Publishing Group.

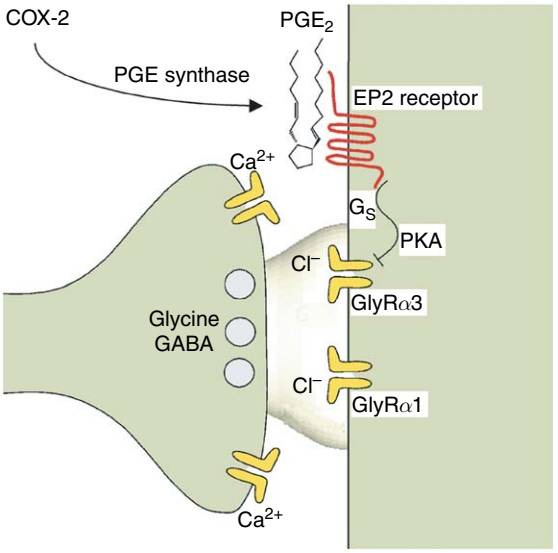

Figure 3 Schematic representation of the intracellular pathway leading to inhibition of glycinergic neurotransmission by PGE_2. PGE_2 activates E-type prostaglandin receptors of the EP2 subtype, which subsequently lead to an increase in intracellular camp and activate protein kinase A (PKA). PKA finally phosphorylates and inhibits GlyRα3. Adapted from Progress in Pain research and Management, vol. 30.

representation of the intracellular pathway that underlies inhibition of glycine receptors by PGE_2. Unlike GlyRα3-containing receptors, homomeric glycine receptors formed by GlyRα1 and heteromeric channels composed of GlyRα1 and GlyRβ are not inhibited by PKA activation and mice carrying a loss-of-function mutation in the GlyRα1 subunit lack a nociceptive phenotype.

Mice lacking GlyRα3 (or EP2 receptors) not only exhibit a nearly complete loss of pain sensitization by spinal PGE_2 but also display nearly identical nociceptive phenotypes in models of inflammatory pain (Figure 4) (Harvey, R. J. *et al.*, 2004, Reinold, H. *et al.*, 2005; see also Zeilhofer, H. U., 2005). Both types of knockout mice develop normal initial thermal and mechanical sensitization, but recover much faster from hyperalgesia than wild-type mice. Inhibition of glycinergic neurotransmission by PGE_2 thus is a key event in the generation of inflammatory pain.

5.27.3.2 Glycine Receptors in the Spinal Control of Neuropathic Pain

A role for cyclooxygenase products has also been proposed for neuropathic pain originating from peripheral nerve injury. However, a significant contribution of prostaglandins to this pain form is discussed controversially and other mechanisms leading to a similar relief from inhibition may be more important (Hösl, K. *et al.*, 2006). Possible mechanisms include an inhibition of synaptic glycine release, reduced responsiveness of postsynaptic glycine receptors, a reduction in the transmembrane chloride gradient rendering the inhibitory tone of GABAergic and glycinergic synaptic input less efficient, and a loss of inhibitory innervation, for

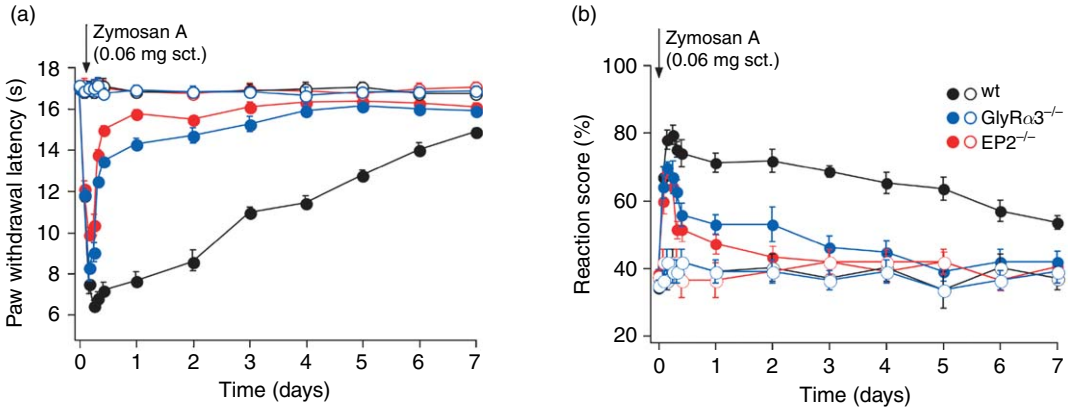

Figure 4 Inflammatory pain sensitization in mice lacking PGE_2-mediated inhibition of glycinergic neurotransmission. An inflammatory response was induced by subcutaneous injection by a yeast extract (zymosan A) into one hind paw. Inflammatory hyperalgesia was assessed by stimulating the inflamed paw either with noxious heat or mechanically with calibrated von Frey filaments. Both mice lacking the EP2 receptor ($EP2^{-/-}$ mice) and mice deficient in GlyRα3 ($GlyR\alpha3^{-/-}$ mice) recovered quickly from inflammatory hyperalgesia. Adapted from Zeilhofer, H. U. 2005. The glycinergic control of spinal pain processing. Cell Mol. Life Sci. 62, 2027–2035.

example due to a selective death of GABAergic or glycinergic interneurons.

There is indeed experimental evidence for all three possibilities, but their contribution to neuropathic pain is not clear. A reduction in the transmembrane chloride gradient in dorsal horn neurons following peripheral nerve injury has been reported by Coull J. A. *et al.* (2003). Peripheral nerve trauma reduced the expression of the potassium chloride exporter KCC2 in dorsal horn neurons. This induced a shift of the chloride equilibrium potential to more depolarized values and rendered inhibitory GABAergic and glycinergic input less efficient. Another extensively discussed report suggests that peripheral nerve injury induces a specific loss of spinal inhibitory GABAergic neurotransmission in the dorsal horn of rats in the chronic constriction injury model and the spared nerve injury model of neuropathic pain (Moore, K. A. *et al.*, 2002). This original report has proposed that the loss of GABAergic input was due to the selective apoptotic death of GABAergic interneurons. Subsequent studies have however suggested that such a loss may not be necessary for the development of hyperalgesia in the chronic nerve injury model of neuropathic pain (Polgar, E. *et al.*, 2003; 2004). Finally, the neuropeptide nocistatin is a specific inhibitor of GABA and glycine release in the spinal cord dorsal horn (Zeilhofer, H. U. *et al.*, 2000) and it increases nociceptive responses in the rat formalin test and in the chronic constriction injury of neuropathic pain after intrathecal injection.

5.27.3.3 Transmitters Facilitating Glycinergic Inhibition

Given that a relief from glycinergic and/or GABAergic inhibition underlies inflammatory and neuropathic pain, one might speculate that transmitters, which facilitate inhibitory transmission might contribute to endogenous antinociception. Several transmitters including ATP (Jang, I. S. *et al.*, 2001; Rhee, J. S. *et al.*, 2000) and norepinephrine (Baba, H. *et al.*, 2000a; 2000b) facilitate glycine release through the activation of P2X receptors and $\alpha2$ adrenoceptors in the spinal cord, respectively. In rat sacral commissural neurons (lamina X) glycinergic membrane currents are potentiated by norepinephrine acting on $\alpha2$ adrenoceptors through a postsynaptic mechanism (Nabekura, J. *et al.*, 1999). These and possibly other similar processes may contribute to endogenous pain-controlling processes. Unfortunately, only very few drugs target glycine receptors and most of them lack the isoform specificity (Laube, B. *et al.*, 2002).

Glossary

at-level pain Pain condition associated with spinal cord injury. Located in dermatomes associated with spinal segments immediately adjacent to the site of injury. Characteristics typically include elevated sensitivity to mechanical and thermal stimuli. Spontaneous sensations (i.e., tingling, numbness, burning) can also be associated with this condition of abnormal sensation. Believed to have a predominately spinal mechanism.

below-level pain Pain condition associated with spinal cord injury. Located in dermatomes associated with spinal segments below the level of injury. Pain is typically spontaneous with characteristics of burning, stabbing, and shooting sensations. Mechanism of below-level pain is believed to involve spinal as well as supraspinal mechanisms.

central injury cascade Pathological events triggered by injury to the central nervous system. Initial events include the extracellular release of excitatory amino acids and the initiation of excitotoxic and inflammatory cascades. Included in this cascade are neurochemical and molecular changes that ultimately lead to changes in the functional properties of spinal and supraspinal sensory neurons.

central sensitization Change in the functional state of central neurons secondary to persistent input or injury-induced elevations of excitatory amino acids leading to the activation of cellular signaling pathways. The end result of this change in functional state is an increase in excitability that can lead to clinical symptoms of allodynia, hyperalgesia, or pain.

pattern generators of pain Dysfunctional neurons with increased excitability are capable of producing abnormal discharges. Collectively the discharges generated from a large population of neurons can form the substrate responsible for the perception of pain.

secondary injury Following an initial mechanical or vascular insult to the brain or spinal cord there is a series of events that are components of the central injury cascade. These events lead to the spread of pathological damage of central neurons beyond the primary insult.

5.28.1 The Condition of Pain Following Spinal Cord Injury

Pain following spinal cord injury (SCI) is one of many challenges associated with the life-threatening consequences of SCI. Over the past 15 years clinical and preclinical studies related to at- and below-level pain have provided an understanding of the spinal and supraspinal mechanism(s) responsible for these conditions. In spite of the fact that loss of sensory and motor function below the level of injury are regarded as the most significant consequences of SCI, the condition of pain has a direct relationship with the ability of patients to regain an optimal level of activity, return to work, and achieve an acceptable quality of life. The impact of spinal injury pain on the healthcare community is evident from studies reporting the incidence of painful sensations at a rate of 60–80% for all SCI patients with nearly 40% reporting severe pain to the extent they would trade any chance of recovering motor function for relief of pain (Nepomuceuno, C. *et al*., 1979; Beric, A., 1990; Britell, C. W. and Mariano, A. J., 1991; Tasker, R. R. *et al*., 1991; Beric, A., 1992; Widerstrom-Noga, E. G. *et al*., 1999a). The functional impact of pain following SCI is further demonstrated by a report describing the challenge of dealing with pain is only surpassed by the decreased ability to walk, loss of sexual function, and bladder and bowel dysfunction (Widerstrom-Noga, E. G. *et al*., 1999b).

5.28.2 Clinical Characteristics of Spinal Injury Pain

Pain associated with SCI is typically bilateral and perceived in anesthetic regions at and below the level of injury. Although changes in sensation above the injury have been reported, there is little evidence supporting the clinical significance of this type of altered sensation. The more common at- and below-level conditions are often referred to as deafferentation pain, dysesthetic pain, or central dysesthesia syndrome (Beric, A. *et al*., 1988; Bonica, J. J., 1991; Yezierski, R. P., 2002). A characteristic of SCI pain that has been consistently documented is the detrimental impact across multiple quality of life domains, including life satisfaction, physical health, and overall handicap. Commonly used descriptors of SCI pain include burning, tingling, numbness, aching, and throbbing. Although it is often difficult to classify different categories of pain, below-level neuropathic pain is the most common and most difficult to treat (Finnerup, N. M. *et al*., 2002). When discussing different classifications of pain it is helpful to have a standard taxonomy. A Task Force of the International Association for the Study of Pain proposed a taxonomy for SCI pain based on the type of pain, location, and putative mechanism of pain onset (Siddall, P. J. *et al*., 2002; Table 1). Having a taxonomy that is accepted and used by clinical and basic research specialists in the fields of pain and spinal injury is essential to achieving a better understanding of different pain conditions.

Table 1 International Association for the Study of Pain proposed classification of spinal cord injury pain

Broad type (tier one)	*Broad system (tier two)*	*Specific structures/pathology (tier three)*
Nociceptive	Musculoskeletal	Bone, joint, muscle trauma, or inflammation
		Mechanical instability
		Muscle spasm
		Secondary overuse syndromes
	Visceral	For example, Renal calculus, bowel dysfunction
		Dysreflexic headache
Neuropathic	(above level)	Compressive mononeuropathies
		Complex regional pain syndromes
	(at level)	Nerve root compression, cauda equina
		Syringomyelia
		Spinal cord trauma/ischaemia
		Dual level cord and root trauma
	(below level)	Spinal cord trauma/ischaemia

Adapted from Siddall, P. J., Yezierski, R. P., and Loeser, J. D. 2002. Taxonomy and Epidemiology of Spinal Cord Injury. In: Spinal Cord Injury Pain: Assessment, Mechanisms, Management (*eds*. R. P. Yezierski and K. Burchiel), pp. 9–24. IASP Press, with permission from International Association for the Study of pain.

The condition of pain following spinal injury has a variable onset depending on the type of pain. Siddall P. J. *et al.* (2003) described the prevalence and onset of different types of pain in a cohort of 100 patients. Musculoskeletal pain (59%) was the most common type of pain followed by at-level (41%) and below-level (34%) neuropathic pain, with visceral pain (5%) the least common type of pain experienced. The mean onset time for any type of pain was 1.6 years with at-level and musculoskeletal pain having the shortest onset times, 1.2 and 1.3 years, respectively. Below-level pain generally had a longer onset time (1.8 years) and visceral pain had the longest (4.2 years). While there has been considerable effort to identify physical factors such as completeness and level of injury that correlate with pain onset, few consistent predictors have been identified (Siddall, P. J. *et al.*, 1999a; Werhagen, L. *et al.*, 2004). A positive relationship between the higher incidence of pain in patients with thoroacolumbar and incomplete lesions has been described (Demirel, G. *et al.*, 1998).

5.28.3 The Research Challenge of Spinal Injury Pain

A major challenge in the study of altered sensation following SCI is the development of appropriate injury models that parallel the human condition. The study of SCI pain has seen the use of several different models, including mechanical trauma, isolated lesions, complete transection, chemical lesions, and ischemic injury, each with pathological components found in the human condition (Wiesenfeld-Hallin, Z. *et al.*, 1994; Siddall, P. J. *et al.*, 1995; Christensen, M. D. and Hulsebosch, C. E., 1997; Yezierski, R. P. *et al.*, 1998; Bruce, J. C. *et al.*, 2002; Scheifer, C. *et al.*, 2002). Behavioral outcome measures used to evaluate injury-induced changes in sensation represents another critical factor in the study of spinal and supraspinal mechanisms of different pain conditions. The majority of behavioral measures used in the study of spinal injury pain rely on responses to mechanical and thermal stimuli to evaluate changes in nociceptive sensitivity. These studies have used a variety of nociceptive reflexes, such as hindpaw withdrawal, that are regulated by segmentally organized spinal mechanisms and are present in spinalized animals. Lick and guard responses have also been used and these responses to nociceptive input depend on spino-bulbo-spinal circuits and are present in decerebrate animals (Woolf, C. J., 1984). Reflex responses are important measures of nociception that have the potential to reveal changes in excitability of spinal circuits, an important consequence of spinal injury. Enhancement of flexion/withdrawal reflexes as reported in the spastic syndrome, however, can be dissociated from chronic below-level pain in individual cases of subtotal SCI (Vierck, C. J. *et al.*, 2002a; 2002). These responses do not represent the component of pain perception that requires cerebral processing of sensation (Mauderli, A. P. *et al.*, 2000) and are more likely to apply to the study of at-level pain that is thought to depend on a spinal mechanism. A misconception in the preclinical study of SCI pain is that stimulation of peripheral dermatomes below the lesion to elicit a reflex response is thought to qualify as the study of below-level pain. The fact is below-level pain is likely to involve supraspinal mechanisms and therefore cannot be studied with reflex-based outcome measures.

Another strategy of behavioral assessment is the use of operant tests that require discrimination between nociceptive and non-nociceptive stimulation and the organization of complex behavioral adaptations to specific environmental contingencies. This approach is believed to provide a more accurate assessment of the pain experience (Vierck, C. J. *et al.*, 2002). The challenge of selecting appropriate behavioral measures is especially evident in the study of below-level pain. If it is assumed that this type of pain requires cortical involvement then to study this type of pain effectively a behavioral measure that relies on activation of cortical structures must be used. The only measures to fit these criteria are operant behaviors that rely on cortical processing for the perception of nociceptive stimuli as well as the planning and execution of learned responses. Acceptance of the differences between responses obtained with operant versus reflex measures represents a major challenge in the study of spinal injury pain, especially studies related to at- and below-level pain.

By far the most significant sensory consequence of spinal injury is below-level pain. This condition has been difficult to study in preclinical models as the pain is typically spontaneous and occurs in parts of the body that are anesthetic. Below-level pain has been attributed to white matter damage, although evidence supports the presence of abnormal activity within the gray matter contributing to below-level hyperalgesia and spontaneous pain behavior. This was demonstrated in experiments with rats and monkeys in which ischemic involvement of spinal gray matter was a critical factor in the development of hyperalgesia after interruption of the spinothalamic tract (Vierck, C. J. *et al.*, 2000). Similarly, quisqualic acid injections in

the spinal gray matter produce below-level hyperalgesia and spontaneous pain behavior without damage to surrounding gray matter (Yezierski, R. P. *et al*., 1998; King, C. D. *et al*., 2006). Clinically, results of a magnetic resonance imaging study in patients with and without below-level pain showed the most common pathological feature of patients with below-level pain was the presence of lesions that included the central core of spinal gray matter (Finnerup, N. M. *et al*., 2003b).

5.28.4 Pathophysiology of Spinal Cord Injury

In order to understand the mechanisms responsible for SCI pain it is important to acknowledge that associated with spinal injury is a cascade of biochemical, molecular, and anatomical changes that collectively impact the survivability and functional integrity of spinal neurons (Figure 1). The clinical consequences associated with SCI, including at- and below-level pain, are believed to result from the influence of this cascade on the functional state of spinal and supraspinal neurons. Therefore to understand the end result (i.e., pain), it is important to appreciate the basic biology of secondary events that precede this condition.

The most obvious pathological changes associated with traumatic or ischemic injury to the spinal cord include, but are by no means limited to, the loss of neurons, damage to surrounding white matter, astrocytic scarring, syrinx formation, and breakdown of the spinal blood–brain barrier (Kakulas, B. A. *et al*., 1990; Bunge, R. P. *et al*., 1993). Also contributing to the progression of tissue damage are secondary injury cascades that include excitotoxic and inflammatory processes (Young, W., 1987; Tator, C. H. and

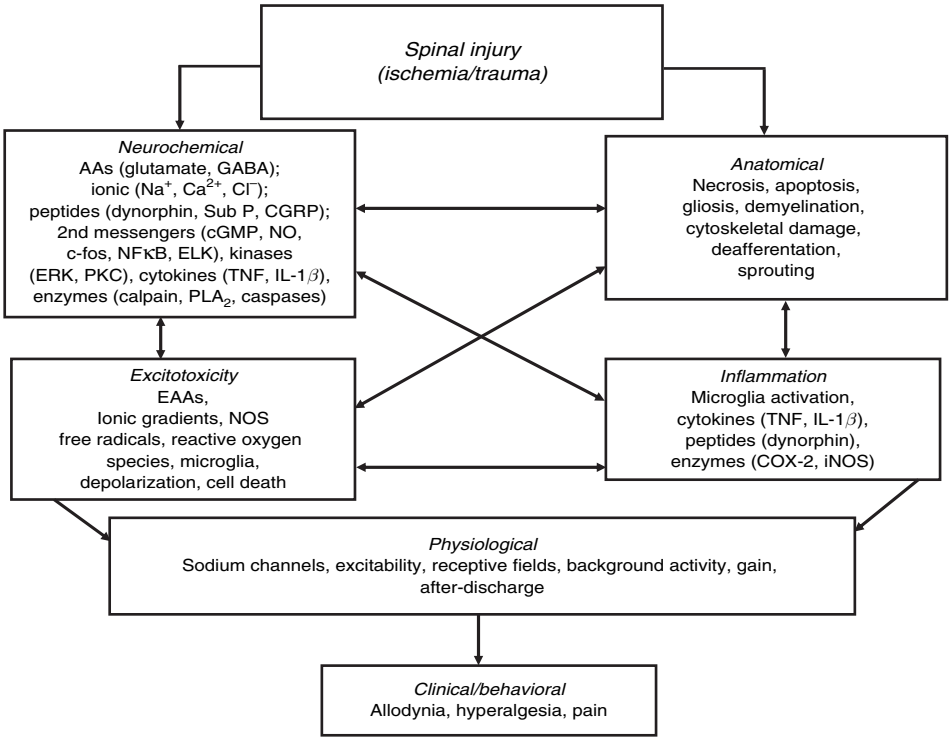

Figure 1 Components of the spinal injury cascade that contribute to the mechanism responsible for the development of pain. Evidence supporting the involvement of this cascade comes from results of clinical and experimental studies involving mechanical, ischemic, and/or chemical models of spinal injury (see text for details). The four major components of the cascade (neurochemical, excitotoxicity, anatomical, and inflammation) are represented as interactive and collectively lead to conditions producing functional changes in spinal and supraspinal neurons. The endpoint of the cascade is the onset of clinical and behavioral symptoms, e.g., allodynia, hyperalgesia, and pain. AAs, amino acids; cGMP, cyclic guanidine monophosphate; CGRP, calcium gene-related peptide; COX-2, cyclo-oxygenase-2; EAA, excitatory amino acid; ELK, ets-like gene; ERK, extracellular signal-regulated kinase; GABA, gamma-aminobutyric acid; IL-1β, interleukin-1β; iNOS, inducible nitric oxide synthase; NFkB, nuclear factor kappa B; NO, nitric oxide; PKC, protein kinase C; PLA_2, phospholipase A2; Sub P, substance P; TNF, tumor necrosis factor. Reproduced from Yezierski, R. P. 2006. Pain Following Spinal Cord Injury: Central Mechanisms. In: Handbook of Clinical Neurology (*eds*. F. Cervero and T. S. Jensen), Vol. 81, pp. 293–307, with permission from Elsevier.

Fehlings, M. G., 1991; Hsu, C. Y. *et al.*, 1994; Regan, R. and Choi, D. W., 1994; Bethea, J. R. *et al.*, 1999). Excitotoxic events following spinal injury are initiated by the well-documented effects of excitatory amino acids (EAAs) that are involved in the secondary pathology, including neuronal degeneration (Faden, A. I. and Simon, R. P., 1988; Nag, S. and Riopelle, R. J., 1990; Hao, J. X. *et al.*, 1991; Yezierski, R. P. *et al.*, 1993; Regan, R. and Choi, D. W., 1994; Wrathall, J. R. *et al.*, 1994). For this reason glutamate has been viewed as one of several putative chemical mediators contributing to the central cascade of secondary pathological changes following injury (Tator, C. H. and Fehlings, M. G., 1991). Inflammation is another major contributor to secondary injury (Bethea, J. R. and Dietrich, W. D., 2002). With the aid of specific histological and immunohistological stains the temporal profile of glia activation (astrocytes, microglial) and the infiltration of macrophages and other inflammatory cell types can be followed. Upregulation of messenger RNA (mRNA) for c-fos, tumor necrosis factor (TNF)-α and dynorphin have also been described following SCI (Yakovlev, A. G. and Faden, A. I., 1994). From this discussion it should be clear that the pathological sequela of SCI is by no means simple neither is it restricted to the site of insult as pathological consequences of SCI have been observed throughout the full extent of the neuraxis (Brewer, K. L. *et al.*, 1997; Jain, N. *et al.*, 1998; Morrow, T. J. *et al.*, 2000).

One of the earliest responses to spinal injury is the breakdown of cellular membranes and subsequent activation of phospholipases. Within minutes of injury, lipid peroxidation and membrane hydrolysis release polyunsaturated fatty acids capable of causing damage, through arachidonic acid and eicosanoid pathways (Anderson, D. and Hall, E., 1993; Tator, C., 1995). Reactive oxygen species (ROS) likewise trigger excitotoxic reactions (glutamate and quinolinate); catecholamine oxidation; mitochondrial breakdown; oxidation of extravasated hemoglobin; neutrophil infiltration; microglial activation; and release of nitric oxide, cytokines, and growth factors. Thus, ROS contribute to the development of a permissive environment for pain following SCI (Kim, H. K. *et al.*, 2004; Hains, B. C. and Waxman, S. G., 2006; Peng, X. M. *et al.*, 2006). Other changes associated with different models of SCI include: afferent sprouting in distant segments (Ondarza, A. B. *et al.*, 2003), upregulation of vanilloid receptor expression (Zhou, Y. *et al.*, 2002), changes in expression of metabotropic glutamate receptors (Mills, C. D. *et al.*, 2001), activation of protein kinases and transcription factors associated with the MAPK signaling pathway (Crown, E. D. *et al.*, 2005; Yu, C. G. and Yezierski, R. P., 2005a), increased NR1 serine phosphorylation of the NMDA receptor (Caudle, R. M. *et al.*, 2003), changes in galanin immunoreactivity (Zvarova, K. *et al.*, 2004), and increased expression of c-fos mRNA (Yakovlev, A. G. and Faden, A. I., 1994; Siddall, P. J. *et al.*, 1999b; Abraham, K. E. and Brewer, K. L., 2001). Furthermore, analysis of molecular events using DNA microarray analysis has shown that 1 h after spinal trauma there are changes in mRNA levels for 165 genes (Nesic, O. *et al.*, 2002; 2005), including those regulating transcription factors, inflammatory processes, cell survival, and membrane excitability. In spite of the wide range of changes associated with spinal injury, the challenge remains to determine which ones have a causal relationship with the mechanism of pain onset, as opposed to being secondary events associated with the process of injury.

An important consideration in the progression of pathological changes associated with spinal injury is the longitudinal extent over which spinal tissue is influenced by the central injury cascade. In a study using agents with neuroprotective properties it was shown that limiting the spread of injury had a significant impact on the expression of pain-related behaviors (Yu, C. G. *et al.*, 2003). This study led to the proposal of a spatial threshold in which a critical distance of spinal tissue must be affected by the secondary injury cascade in order for pain behaviors to develop. Therefore, a critical determinant underlying the expression of pain following SCI may be a combination of specific injury related events together with the longitudinal spread of these events within the cord (Yezierski, R. P., 2000; Gorman, A. L. *et al.*, 2001). Identifying the mechanism responsible for the spread of injury may provide valuable insight into the development of different pain conditions. Given the permissive microenvironment for the development of pain associated with the wide spectrum of molecular, anatomical, neurochemical, and functional changes that occur following spinal injury it is not surprising that pain is a common clinical finding following injury.

5.28.5 Mechanism(s) of Pain Following Spinal Injury

The precise mechanism(s) underlying different types of neuropathic pain (at- and below-level) associated with spinal injury remain to be determined. While

below-level pain is considered to have a central mechanism involving cortical and subcortical structures, at-level pain may have peripheral and central components. Unfortunately, little is known about the potential peripheral contribution to spinal injury pain. Little is also known about the role of the autonomic nervous system (ANS) in the development of different pain conditions following injury. Given the likely damage to sympathetic and parasympathetic neurons following injury and the contribution of the ANS to chronic pain states, there is a need for studies focusing on the role of autonomic dysfunction in the development of spinal injury pain.

Results of experimental studies have provided evidence to construct a working model for at- and below-level behavioral effects of SCI. This model includes a combination of six conditions: (1) loss of spinal inhibitory neurons, (2) emergence of spinal generators and supraspinal amplifiers of abnormal activity, (3) dependence on a population of NK-1R expressing neurons in the superficial dorsal horn, (4) longitudinal progression of a secondary injury cascade, (5) reorganization of supraspinal structures, and (6) activation of the MAPK cell signaling pathway (Figure 2).

5.28.5.1 Loss of Inhibitory Tone

A critical factor in the onset of painlike behaviors following SCI is the loss of inhibitory influences within the injured spinal cord (Wiesenfeld-Hallin, Z., *et al.* 1994). The loss of inhibitory control allows for the recruitment of surrounding neurons and intensification and spread of abnormal sensations, including pain. Support for this conclusion comes from four lines of evidence: (1) following ischemic injury there is an increased excitability of WDR neurons that is reversed by the $GABA_B$ receptor agonist baclofen (Hao, J. X. *et al.*, 1992), (2) hypersensitivity to peripheral stimuli can be produced in normal animals by the intrathecal administration of gamma-aminobutyric acid (GABA) receptor antagonists (Yaksh, T. L., 1989; Hao, J.-X. *et al.*, 1994),

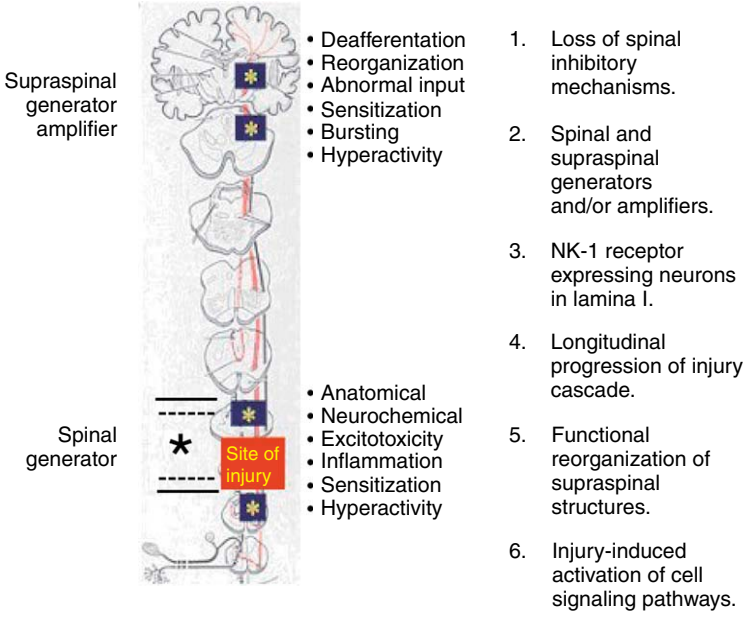

Figure 2 Summary of six different injury-induced changes contributing to the development of at- and below-level pain associated with spinal cord injury. A spinal pain generator evolves due to the collective impact of anatomical, neurochemical, inflammatory, and excitotoxic changes that result in the increased excitability of spinal sensory neurons. Specific changes contributing to the development of the spinal generator include loss of inhibitory mechanisms, the longitudinal progression of the spinal injury cascade, and the injury-induced activation of cell-signaling pathways. At supraspinal levels the presence of a generator/amplifier mechanism emerges as a result of the loss of afferent input from spinal segments below the level of injury (deafferentation). The functional impact of this and other injury-induced changes at supraspinal levels (e.g., sprouting, unmasking of connections) results in the activation of supraspinal regions by input from somatotopically inappropriate regions of the cord and the referral of pain sensations to dermatomes below the level of injury. Reproduced from Yezierski, R. P. 2006. Pain Following Spinal Cord Injury: Central Mechanisms. In: Handbook of Clinical Neurology (*eds*. F. Cervero and T. S. Jensen), Vol. 81, pp. 293–307, with permission from Elsevier.

(3) decreased numbers of GABA-positive neurons following ischemic spinal injury (Zhang, A.-L. *et al.*, 1999), and (4) administration of drugs that prolong the action of inhibitory neurotransmitters (i.e., tricyclic antidepressants) are effective in the short-term treatment of spinal injury pain (Tunks, E., 1986; Lejon, G. and Boivie, J., 1991; Boivie, J., 1994). Although existing evidence supports the decreased inhibitory influence of GABAergic neurotransmission in altering the functional properties of neurons in the injured cord, not to be overlooked in this process is a decreased influence of supraspinal inhibitory pathways that may be disrupted following injury. Alterations in descending serotonergic projections above and below the site of injury have led to the suggestion that loss of inhibitory influences below the injury may contribute to the increased excitability of neurons while an increase in serotonergic projections above the injury may contribute, through descending facilitation, to a change in functional state of neurons above the level of injury (Oatway, M. A. *et al.*, 2004).

5.28.5.2 Pattern Generators of Pain

Another component of the pathophysiological sequela of SCI that is thought to contribute to the onset of altered sensations is the emergence of a pattern generating mechanism (spinal and supraspinal). Several observations are consistent with the pattern generating hypothesis: (1) existence of focal regions of hyperactivity in the spinal cord and thalamus of spinal injured patients (Loeser, J. D. *et al.* 1968; Edgar, R. E. *et al.*, 1993; Lenz, F. A. *et al.*, 2000); (2) effectiveness of spinal anesthesia in alleviating pain when delivered proximal to the site of injury (Pollock, L. J. *et al.*, 1951; Botterell, E. H. *et al.*, 1953; Loubser, P. G. and Donovan, W. H., 1991); and (3) sensitization and prolonged after-discharges of spinal and supraspinal sensory neurons following SCI (Hao, J. X. *et al.*, 1992; Yezierski, R. P. and Park, S. H., 1993; Lenz, F. A. *et al.*, 2000; Drew, G. M. *et al.*, 2001; Hains, B. C. *et al.*, 2003b; Hoheisel, U. *et al.*, 2003; Hao, J. X. *et al.*, 2004; Hains, B. C. *et al.*, 2005). Consistent with an involvement of neuronal hyperexcitability as a component of the spinal and possibly supraspinal mechanism of SCI pain are results of pharmacological studies. For example, lidocaine and ketamine, two drugs that reduce membrane excitability and glutamate receptor activation are effective in treating SCI pain (Loubser, P. G. and Donovan, W. H., 1991; Eide, P. K. *et al.*, 1995; Attal, N. *et al.*, 2000). Efforts to increase inhibition with either baclofen or propofol are also effective (Herman, R. M. *et al.*, 1992; Canavero, S. *et al.*, 1995). The anticonvulsant lamotrigine that affects sodium channels involved in hyperexcitability is also suggested to be effective in SCI patients with spontaneous and evoked pain (Finnerup, N. M. *et al.*, 2002).

Consistent with the excitability hypothesis and involvement of neurons in the superficial dorsal horn in spontaneous and evoked pain behaviors, are clinical reports of abnormal focal hyperactivity within the superficial laminae of the injured cord (Edgar, R. E. *et al.*, 1993). Microcoagulation of these hyperactive areas in the dorsal root entry zone (DREZ) at depths of 1–2 mm, representing Rexed's laminae I–II, results in a significant diminution of pain. A variant of the DREZ technique utilizing intramedullary recordings of C-fiber evoked responses to guide DREZ lesioning allows for the somatotopic mapping of the DREZ with regard to the generation of central deafferentation pain. In 25 patients where this technique was used, 84% received complete pain relief (Falci, S. *et al.*, 2002). An involvement of this region in the generation of pain is further supported by a report where elimination of NK-1R-expressing neurons in the superficial dorsal horn resulted in not only the prevention of spontaneous pain behavior, but also the reversal of the behavior once it had been initiated (Yezierski, R. P. *et al.*, 2004).

Injury-induced changes contributing to increased excitability of spinal circuitry has also been attributed to an increased expression of the $Na_v1.3$ sodium channel in spinal segments L3–L5 following contusion injury at T9 (Hains, B. C. *et al.*, 2003a). Upregulation of $Na_v1.3$ expression at sites remote from the epicenter of injury was shown to have a significant role in producing increased excitability of spinal multireceptive neurons recorded in L3–L5. Efforts to block these changes after injury showed that responses of neurons in animals treated intrathecally with antisense oligodeoxynucleotides targeting $Na_v1.3$ decreased expression of $Na_v1.3$ mRNA and protein, reduced hyperexcitability of multireceptive neurons, and attenuated mechanical allodynia and thermal hyperalgesia after SCI. Similarly, upregulation of $Na_v1.3$ sodium channels in thalamic neurons has also been shown to contribute to changes in the electrophysiological properties of these neurons (Hains, B. C. *et al.*, 2005). Thus, changes in the functional state of sensory neurons secondary to upregulation of sodium channels provides the mechanism for a pain generator in the injured cord as well as an amplifier of abnormal activity in thalamus.

The contribution of abnormal spinal input together with the effects of deafferentation (secondary to loss of spinal projection neurons) and upregulation of sodium channels could result in the development of abnormal generators or amplifiers of spinal input at supraspinal sites (Vierck, C. J., Jr., 1991). The transient relief of below-level pain in humans following application of local anesthetic to the proximal stump of a spinal lesion (Pollock, L. J. *et al.*, 1951) suggests that the presence of a spinal generator plays a significant role in maintaining chronic below-level pain. Thus, a combination of supraspinal changes secondary to deafferentation, and the emergence of a spinal generator of abnormal activity are two significant events that may contribute to the development and maintenance of below-level pain. Recently, the report of elevated blood flow in thalamic nuclei (possibly reflecting changes in the functional state of neurons) lend additional support to the thalamic involvement in the supraspinal response to SCI and to the mechanism of injury-induced pain (Morrow, T. J. *et al.*, 2000).

5.28.5.3 Cell Signaling Pathways: Synaptic Plasticity and Functional State

Another consideration for the mechanism of chronic pain following spinal injury is synaptic plasticity and changes in the functional state of spinal neurons. A significant response to injury of central or peripheral origin is the cellular response believed to contribute to the sensitization of spinal neurons (Woolf, C. J. and Csotigan, M., 1999; Woolf, C. J., 1992; Willis, W. D., 2002). Synaptic plasticity in the central nervous system is thought to be part of central sensitization and together with the long-term changes in functional state of spinal sensory neurons represents a potential mechanism for persistent pain (Ji, R. R. *et al.*, 2003). Unfortunately, we are only at the beginning of understanding the biochemical and molecular events underlying long-term functional plasticity and their role in chronic pain. Included in the events thought to be involved in producing long-term changes are: (1) phosphorylation of regulatory proteins (as well as dephosphorylation of others), (2) positive and negative regulation of gene transcription, (3) injury-induced synthesis of proteins (as well as reduced synthesis of others), (4) strengthening of some and weakening of other connections (synaptic long-term potentiation, sprouting, and pruning), and (5) the death or rescuing of neurons. These neuronal changes share initiating events such as glutamate-induced elevations in calcium, maintaining events (nitric oxide synthesis, activation of protein kinases), perpetuating forces (activation of cyclic AMP response element-binding (CREB), nuclear factor kappa B (NF-κB), and terminal results (altered synaptic efficacy). In contrast to cellular events underlying persistent pain of peripheral origin, the mechanism underlying long-term plasticity associated with pain of central origin remains largely unexplored.

Important events contributing to the development of injury-induced pain are found in a construct of central sensitization and plasticity (Woolf, C. J. and Csotigan, M., 1999; Ji, R. R. and Woolf, C. J., 2001; Ji, R. R. *et al.*, 2003). Hypersensitivity is believed to be a consequence of early posttranslational changes as well as later transcription-dependent changes in effector genes. Neuroplasticity resulting from these events includes activity-dependent changes in neurons and specific signaling molecules in signal transduction pathways. These changes likely contribute to alterations in the basal state of excitability that ultimately contributes to the development of spinal pain generators and possibly supraspinal amplifiers.

Examples of cell signaling events following spinal injury were described in a study of changes in the mitogen-activated protein kinase (MAPK) signaling pathway following excitotoxic spinal injury including: (1) increased phosphorylation of ERK1/2, (2) increased activation of NF-κB and phosphorylation of ELK-1, and (3) increased gene expression for the NK-1 receptor and NR1 and NR-2A subunits of the NMDA receptor (Yu, C. G. and Yezierski, R. P., 2005a). Blockade of the MAPK cascade with the MEK inhibitor PD98059 inhibited phosphorylation of ELK-1, activation of NF-κB, and gene expression of NR1, NR-2A, and NK-1R, and prevented the development of spontaneous pain behavior. Injury-induced elevations in spinal levels of EAAs thus lead to the activation of the ERK → ELK-1 and NF-κB signaling cascades and the transcriptional regulation of receptors important in the development of chronic pain. Blockade of these intracellular kinase cascades prevents the onset of injury-induced pain behavior. Similar changes in different components of the MAPK signaling pathway have been described in the diencephalon following injury (Yu, C.-G. and Yezierski, R. P., 2005b). The persistent upregulation of CREB in spinothalamic tract cells is another example of how cell signaling events are affected by SCI (Crown, E. D. *et al.*, 2005).

The above results suggest that many of the same molecular changes described as activity-dependent following peripheral nerve and tissue injury can also

be induced following central injury, that is, injury dependent. This suggests that the mechanism responsible for the increased excitability of spinal neurons following spinal injury may be similar to the well-documented activity-dependent mechanism induced by damage to peripheral tissue and/or nerves, a mechanism resulting in the activation of intracellular kinase cascades and ultimately long-term changes in synaptic efficacy and neuronal excitability. The end result of these events is the emergence of a hyperexcitable pain-generating mechanism.

5.28.5.4 Supraspinal Changes Following Spinal Cord Injury

One cannot discuss SCI without acknowledging the most fundamental of all anatomical facts and that is the connection between the brain and spinal cord. Following injury to the cord it has been well documented that there are multiple changes (e.g., anatomical, molecular, functional) that occur within cortical and subcortical structures. Changes in supraspinal structures could potentially contribute to the central mechanism responsible for the onset and progression of injury-induced pain behaviors. Studies carried out include an evaluation of changes in forebrain blood flow (Morrow, T. J. *et al.*, 2000), and evaluation of opiate transmitters in selected supraspinal sites (Abraham, K. E. *et al.*, 2001). In the study by Morrow T. J. *et al.* (2000) significant increases in regional cerebral blood flow were found in seven of 22 supraspinal structures examined, including the arcuate nucleus, hindlimb region of S1 cortex, parietal cortex and the thalamic posterior, ventral posterior medial and lateral nuclei. All of these structures have well-documented roles in sensory processing. These studies complement clinical observations showing similar changes in thalamic blood flow following SCI (Ness, T. J. *et al.*, 1998), alterations in the chemical profile of ventroposterolateral thalamus in patients with SCI pain (Pattany, P. M. *et al.*, 2002), and reports of hyperactive foci of thalamic activity in SCI patients with spontaneous burning pain (Lenz, F. A. *et al.*, 2000; Ohara, S. *et al.*, 2002).

Additional support for supraspinal changes contributing to the mechanism of spinal injury pain is the work from Brewer and colleagues focusing on changes in peptidergic transmitter systems at supraspinal levels following excitotoxic SCI (Abraham, K. E. *et al.*, 2001). Preproenkephalin (PPE) and preprodynorphin (PPD) expression was shown to increase in cortical regions associated with nociceptive function; PPE in the cingulate cortex and PPD in the parietal cortex, both ipsilateral and contralaterally at various timepoints following injury. Increases in PPD were significant in animals that developed spontaneous pain behaviors versus those that did not. PPE expression in the anterior cingulate cortex and PPD expression in the contralateral parietal cortex were significantly higher in animals with spontaneous pain behaviors versus those without pain behaviors. The important conclusion from these reports is that following spinal injury there are significant changes in selected supraspinal sites including somatosensory structures putatively involved in pain processing. These results are consistent with a recent report in humans using proton magnetic resonance spectroscopy showing changes in the thalamic concentrations of selected metabolites in SCI patients with pain (Pattany, P. M. *et al.*, 2002). Thus there is likely to be a significant supraspinal component to the mechanism responsible for the development of below-level SCI pain. Understanding the role of these supraspinal changes in the development of pain, especially below-level, remains a challenge for future studies.

5.28.6 Future Directions

An important realization of clinical and experimental studies directed toward understanding the mechanism(s) of SCI pain is the importance of identifying the critical events responsible for the onset of this condition. Continued studies focusing on different components of secondary excitotoxic and inflammatory cascades ultimately responsible for the dysfunction of spinal and supraspinal neurons are essential to the design of more effective interventions. The condition of pain associated with spinal injury is unlikely to have a simple mechanism that relies exclusively on any one consequence of injury. It is more probable that several components of a central injury cascade contribute to the development and maintenance of different pain states. The precise mechanism is likely to depend on the nature of the injury and progression of pathological and biochemical changes along the rostrocaudal axis of the cord, and include anatomical, molecular, and functional changes occurring in supraspinal structures. The mechanism is likely to include the combination of deafferentation resulting from spinal lesions combined with tonic excitatory input from a generator of abnormal activity in or around the epicenter of gray matter damage, that is, penumbral region. This

input reaches deafferented supraspinal processing centers (via undamaged projections or multisynaptic pathways) and contributes to the abnormal discharge and/or amplification of activity ultimately leading to the perception of pain (at- or below-level).

In conclusion, well-established animal models indicate that at-level SCI pain results from excitotoxic/ischemic damage to the spinal gray and white matter. Experimental models have identified putative mechanisms for generation of at-level pain and have suggested a number of potential therapeutic approaches, including pharmacological strategies targeting inhibitory systems or spinal mediators of cell survival. Of special importance is control over secondary signaling pathways along with injury-induced chemical and molecular changes that modulate neuronal excitability. Additionally, current evidence suggests that restricting the extent of excitotoxic injury after traumatic SCI might prevent the development of below-level neuropathic pain, both by reducing excitatory influences and by limiting gray matter damage. In contrast, below-level neuropathic pain does not appear to result only from interruption of spinothalamic projections to rostral targets, but is potentiated by interruption and/or activation of other pathways, including propriospinal systems. Important questions related to different pain conditions associated with SCI include the role of glia activation and descending modulation (i.e., facilitation) in the initiation and maintenance of different pain states. It will also be important to determine if there are autonomic and peripheral components to the mechanism of SCI pain. Central and/or peripheral contributions to injury-induced visceral pain is another area requiring additional study. Continued use of available animal models of at- and below-level pain should provide an increasingly precise definition of mechanism(s) and potential therapeutic targets for these conditions.

Glossary

synaptic efficacy, syn. synaptic strength Magnitude of postsynaptic current or potential in response to a presynaptic action potential. Synaptic strength may be modified by pre- and/or postsynaptic modulation.

long-term potentiation (LTP) Enduring increase in synaptic efficacy.

long-term depression (LTD) Enduring decrease in synaptic efficacy of a putatively nonpotentiated synapse.

depotentiation Enduring decrease of synaptic efficacy of a previously potentiated synapse, that is, reversal of LTP.

LTP induction Cellular signal transduction pathways which lead to LTP.

LTP maintenance Cellular signal transduction pathways which are involved in stabilizing established LTP.

spinal field potential Extracelluar electrical field which is mainly generated by simultaneous postsynaptic currents in spinal cord neurons in response to a brief stimulus, similar to evoked potentials in cerebral cortex.

5.29.1 Introduction

Long-term potentiation (LTP) is defined as the persistent increase in synaptic strength (Bliss, T. V. P. and Collingridge, G. L., 1993; Malenka, R. C. and Nicoll, R. A., 1999). Repetitive use of a synapse often leads to LTP which may last for a few hours only or for days to months. Synaptic strength may also be reduced for prolonged periods of time which is called long-term depression (LTD) when induced in a normal synapse or depotentiation when elicited in a previously potentiated synapse, that is, in the maintenance phase of LTP (Huang, C. C. and Hsu, K. S., 2001).

LTP has been most intensively studied in hippocampus where it is considered a fundamental cellular model of learning and memory formation (Bliss, T. V. P. and Collingridge, G. L., 1993; Malenka, R. C. and Nicoll, R. A., 1999). LTP has also been shown in pain pathways at synapses between primary afferent Aδ- or C-fibers and spinal dorsal horn neurons and is one of the proposed cellular mechanisms of pain amplification (Moore, K. A. *et al.*, 2000; Sandkühler, J., 2000). The potential consequences of LTP in pain pathways are manifold: (1) after LTP is established, suprathreshold excitatory input will now evoke stronger excitation of nociceptive neurons. Thus, LTP at nociceptive synapses may underlie hyperalgesia; (2) previously subthreshold excitatory input, from the subliminal fringe of a neurons' receptive field may now elicit action potential firing. This may widen painful areas and contribute to hyperalgesia as well; and (3) some spinal dorsal horn neurons receive subthreshold input from somatotopically inappropriate body areas, for example, the contralateral body half. LTP anywhere

along this subliminal input path may cause mirror image pain or radiating pain. LTP at nociceptive synapses may, however, not significantly lower pain thresholds and is therefore not considered a likely mechanism of allodynia.

The most direct way to ascertain LTP in pain pathways is to measure monosynaptically evoked postsynaptic currents or potentials. So far this has only been done *in vitro* by recording Aδ- or C-fiber-evoked excitatory postsynaptic currents or potentials from dorsal horn neurons in response to electrical stimulation of dorsal roots. When postsynaptic currents are elicited synchronously in a sufficient number of neighboring neurons, electrical field potential are generated which are strong enough to be detected with extracellular microelectrodes (Schouenborg, J., 1984). Thus, to evaluate changes in synaptic strength, C-fiber-evoked field potentials can be recorded in superficial spinal dorsal horn *in vivo* and *in vitro* in response to supramaximal electrical stimulation of a dorsal root or a sensory nerve, for example, the sciatic nerve. If, however, events downstream to postsynaptic currents are recorded, such as action potential discharges, polysynaptically evoked responses, withdrawal reflexes or pain ratings, LTP can no longer be assessed directly. These measures are, however, indispensable to evaluate the functional consequences of LTP in pain pathways. This is discussed in greater detail elsewhere (Sandkühler, J., 2007).

5.29.2 Induction of Long-Term Potentiation in Pain Pathways

In superficial spinal lamina I, LTP is selectively induced in a group of nociceptive specific neurons which express the NK1 receptor for substance P and which project to the brain (see Figure 1; Ikeda, H. *et al.*, 2003; Ikeda, H. *et al.*, 2006). This group of neurons plays a key role in hyperalgesia following inflammation and nerve injury (Mantyh, P. W. *et al.*, 1997). In spinal cord LTP can be induced in different ways, for example, by electrical nerve stimulation , by nerve injury, or peripheral noxious events. Stimulation within the innervation territory of a sensory nerve, for example, with chemical irritants, or by inflammation may also trigger LTP at C-fiber synapses. All conditioning stimuli tested so far which induce LTP at Aδ-synapses (Randic, M. *et al.*, 1993) and/ or C-fiber synapses (Liu, X. G. and Sandkühler, J., 1995) may also cause hyperalgesia in experimental animals.

1. Electrical nerve stimulation: LTP has been induced by conditioning high intensity, high frequency burst-like stimulation (HFS, typically given as 50–100 Hz bursts for 1 s at C-fiber strength) *in vitro* (Randic, M. *et al.*, 1993; Hamba, M. *et al.*, 2000; Ikeda, H. *et al.*, 2000; Ikeda, H. *et al.*, 2003) and *in vivo* (Liu, X. G. and Sandkühler, J., 1997; Miletic, G. and Miletic, V., 2000; Ma, J. Y. and Zhao, Z. Q., 2001; Zhang, H. M. *et al.*, 2001). Stimulation intensity must be sufficient to recruit C-fibers; stimulation at A-fiber intensity is ineffective to induce LTP at C-fiber synapses (Liu, X. G. and Sandkühler, J., 1997). C-fibers do, however, discharge at such high frequencies only rarely. Thus, the pathological relevance of HFS-induced LTP can be challenged.
2. Recent studies show that not only HFS but also conditioning low frequency stimuli at 2–10 Hz which is well within the frequency band of C-fiber discharges during inflammation or tissue injury causes robust LTP, both, *in vivo* and *in vitro* (Terman, G. W. *et al.*, 2001; Ikeda, H. *et al.*, 2006)/electrical stimulation of sciatic nerve at C-fiber intensity (2 Hz, 2 min) induces robust LTP to 300% of control values which is not reversible within the recording periods of up to 18 h (Figure 1; Ikeda, H. *et al.*, 2006).
3. Electrical stimulation of nerves evokes regular and highly synchronous discharges which is not typical for naturally occurring, irregular nonsynchronous discharge patterns. Thus, it was important to show that LTP can also be induced by excitation of sensory nerve endings, for example, by subcutaneous injection of either capsaicin or formalin. In animals with spinal cord and descending pathways intact, intraplantar, s.c. injections of capsaicin or formalin induce slowly rising LTP (Figure 1; Ikeda, H. *et al.*, 2006).
4. Finally, with descending spinal pathways interrupted noxious skin heating and acute nerve injury also causes LTP at C-fiber synapses (Sandkühler, J. and Liu, X., 1998). This demonstrates that naturally occurring, low frequency, irregular, and nonsynchronous afferent barrage can cause synaptic plasticity in pain pathways.

LTP of C-fiber-evoked spinal field potentials can also be induced pharmacologically. In spinalised rats, topical application of *N*-methyl-D-aspartate (NMDA), substance P or neurokinin A induces LTP (Liu, X. G. and Sandkühler, J., 1998). In intact animals, spinal

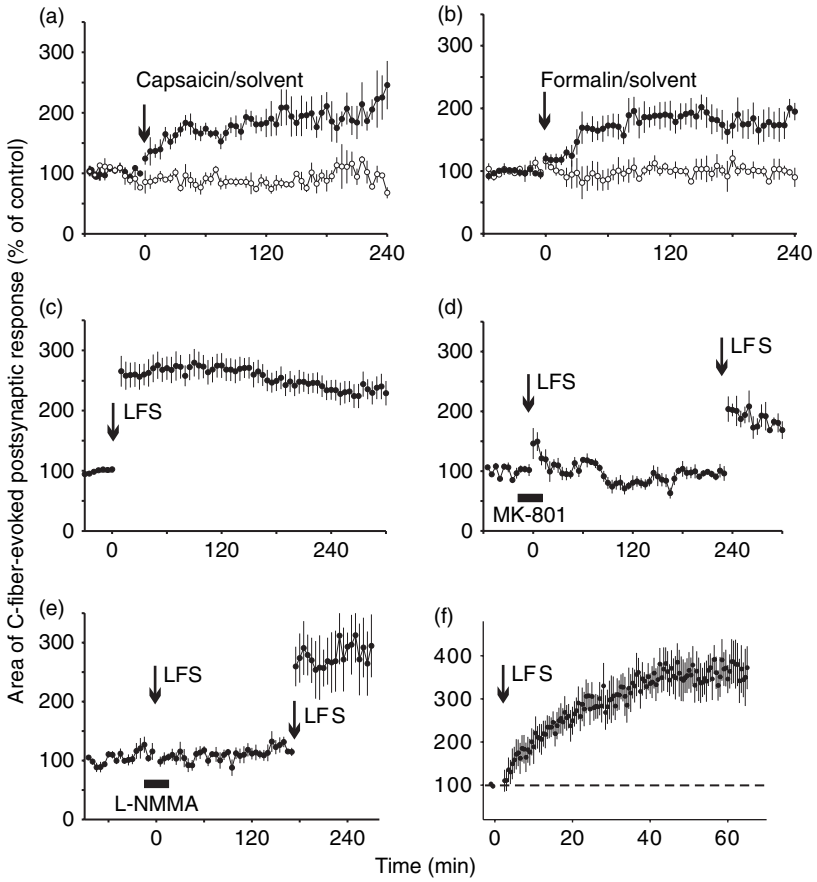

Figure 1 LTP can be induced by natural, low-frequency afferent barrage evoked by inflammation of peripheral tissue *in vivo* and by low-frequency stimulation of dorsal root afferents *in vitro*. Mean time courses of C-fiber-evoked field potentials recorded extracellulary in superficial spinal dorsal horn in response to electrical stimulation of left sciatic nerve of deeply anaesthetized adult rats with spinal cords and afferent nerves intact (a)–(e). Subcutaneous injections of transient receptor potential vanilloid 1 channel agonist capsaicin (1%, 100 µl, $n = 5$, (a) or formalin (5%, 100 µl, $n = 6$), (b) into the glabrous skin at the ipsilateral hind paw, within the innervation territory of the sciatic nerve at time zero (arrows) induced LTP (closed circles), while injections of the respective solvents (open circles) had no effects ($n = 3$ in each group). Conditioning electrical LFS (2 Hz, 2 min at C-fiber intensity) of sciatic nerve at time zero (arrow) also induced LTP ($n = 28$), (c) which was prevented by NMDA receptor antagonist MK-801 (3 mg kg^{-1}, i.v.-infusion over 30 min: horizontal bar, $n = 5$); (d) a second conditioning LFS four hours later (arrow) was partially effective in inducing LTP. NOS inhibitor L-NMMA (100 mg kg^{-1} h^{-1}, i.v., horizontal bar, $n = 5$); (e) also blocked LTP induction. This block was fully reversible as shown by a second LFS 3 h later (arrow). Similarly, LFS of dorsal roots at C-fibre strength induces robust LTP at synapses between C-fibre afferents and lamina I neurons with a projection to the midbrain periaqueductal gray (PAG) in a rat spinal cord–dorsal root preparation ($n = 18$). Adapted from Ikeda, H., Stark, J., Fischer, H., Wagner, M., Drdla, R., Jäger, T., and Sandkühler, J. 2006. Synaptic amplifier of inflammatory pain in the spinal dorsal horn. Science 312, 1659–1662.

application of dopamine D1/D5 or protein kinase A activators but not D2 receptor agonists selectively induces protein synthesis-dependent late phase of LTP (Yang, H. W. *et al.*, 2005).

5.29.3 Signal Transduction Pathways

The signal transduction pathways which lead to LTP in spinal dorsal horn largely overlap with those involved in hyperalgesia in behaving animals. At C-fiber synapses, LTP induction requires co-activation of ionotropic glutamate receptors of the NMDA type (Randic, M. *et al.*, 1993; Liu, X. G. and Sandkühler, J., 1995; Ikeda, H. *et al.*, 2003; 2006; see, however, Hamba, M. *et al.* 2000) and group I but not group II or group III metabotropic glutamate receptors (mGluRs) (Hamba, M. *et al.*, 2000; Zhong, J. *et al.*, 2000; Azkue, J. J. *et al.*, 2003). LTP-inducing conditioning stimuli release substance P in spinal cord (Afrah, A. W. *et al.*, 2002) and activation of

NK1 receptors for substance P and NK2 receptors for neurokinin A are required for LTP induction (Liu, X. G. and Sandkühler, J., 1997). Opening of T-type voltage gated calcium channels is also necessary (Ikeda, H. *et al.*, 2003; 2006). All this leads to an activity-dependent rise in intracellular calcium ion concentration and activation of calcium-dependent signal transduction. The magnitude of HFS-induced LTP of C-fiber-evoked responses is linearly correlated with the rise in postsynaptic $[Ca^{2+}]_i$ (Ikeda, H. *et al.*, 2003). Blockade of calcium rise in the postsynaptic neuron or calcium-calmodulin-dependent protein kinase II prevents LTP induction (Ikeda, H. *et al.*, 2003; see, however, Hamba, M. *et al.*, 2000; Yang, H. W. *et al.*, 2004). Activation of group I mGluRs may activate phospholipase C (PLC) pathway leading to either protein kinase C activation or formation of inositol-1,4,5-trisphosphate (IP_3). Blockade of either PLC, PKC, or IP_3 receptors all abolish LTP induction (Ikeda, H. *et al.*, 2003).

Activation of NMDA, NK1, or NK2 receptors is not necessary for maintenance of LTP (Liu, X. G. and Sandkühler, J., 1997). Maintenance of the late phase of LTP which starts about 3 h after induction requires, however, *de novo* protein synthesis (Hu, N. W. *et al.*, 2003).

5.29.3.1 Long-Term Potentiation Induction is Context Sensitive

Induction of LTP not only depends upon the activity patterns at the presynaptic terminals, but also on the functional state of the postsynaptic neurons, namely the level of postsynaptic inhibition. Under conditions of impaired inhibition, previously ineffective presynaptic activity may now induce LTP and protocols which normally induce LTD may then cause LTP. *In vitro*, both, Aδ-fiber-evoked (Randic, M. *et al.*, 1993) and C-fiber-evoked (Ikeda, H. *et al.*, 2003) responses are potentiated by conditioning 100 Hz stimulation of dorsal roots when postsynaptic neurons are mildly depolarized to −70 to −60 mV. The same conditioning stimulation induces, however, LTD of Aδ-fiber-evoked responses if cells are hyperpolarized to −85 mV, suggesting that the direction of synaptic plasticity is voltage dependent (Randic, M. *et al.*, 1993).

Spinal Aβ-/Aδ-fiber-evoked field potentials are depressed by conditioning 50 Hz stimulation of sciatic nerve. After blockade of $GABA_A$ receptors with bicuculline the same conditioning stimulus now produces LTP rather than LTD (Miletic, G. and Miletic, V., 2001). In animals with a nerve injury, inhibition in spinal cord may be impaired. Conditioning stimulation at 50 Hz produces a short lasting potentiation followed by LTD in control animals but LTP in animals with a chronic constriction injury of sciatic nerve (Miletic, G. and Miletic, V., 2000). Topical application of muscimol (10 μg) to spinal cord prevents tetanus-induced LTP of A-fiber-evoked field potentials in animals with a nerve injury. In the presence of $GABA_A$ receptor agonist muscimol the same conditioning stimulation evokes an LTD rather than an LTP (Miletic, G. *et al.*, 2003).

Pharmacological activation of spinal NMDA receptors and NK1 or NK2 receptors is insufficient to induce LTP in intact animals. When descending pathways, which are mainly inhibitory in acute preparations, are cut, then the same receptor agonists now trigger LTP (Liu, X. G. and Sandkühler, J., 1998). This confirms that level of postsynaptic inhibition regulates induction and polarity of synaptic plasticity. Some pharmacological induction protocols do not require any presynaptic stimulation which suggests that LTP can be induced in the absence of presynaptic activity. This may be relevant when neuromodulators such as substance P diffuse to distant, inactive synapses (volume transmission), which is a potential mechanism of spreading synaptic plasticity in the spinal cord.

Functional blockade of glial cells by i.t. administration of fluorocitrate changes the direction of HFS induced plasticity of C-fiber-evoked potentials. When HFS is given 1 h, but not 3 h after fluorocitrate LTD rather than LTP is induced (Ma, J. Y. and Zhao, Z. Q., 2002). The mechanism of this switch in polarity of synaptic plasticity is presently unknown but recent evidence suggests that glial cell-derived nitric oxide is liberated via activation of type 1 mGluRs and triggers LTP (Ikeda, H. and Murase, K., 2004).

5.29.4 Prevention of Long-Term Potentiation

LTP of C-fiber-evoked field potentials *in vivo* is not affected by deep (surgical) level of anesthesia with urethane, isoflurane, or sevoflurane in mature rats (Benrath, J. *et al.*, 2004). LTP is, however, prevented by low-dose intravenous infusion of μ-opioid receptor agonist fentanyl (Benrath, J. *et al.*, 2004). Similarly, spinal field potentials elicited by stimulation in the tract of Lissauer in spinal cord slices is blocked by DAMGO, a more specific agonist at these receptors

(Terman, G. W. *et al.*, 2001). Spinal application of Zn^{2+} also blocked LTP induction *in vivo* (Ma, J. Y. and Zhao, Z. Q., 2001).

5.29.5 Reversal of Long-Term Potentiation

Brief, high-frequency conditioning of sciatic nerve at Aδ-fiber intensity partially and temporarily reverses LTP of C-fiber-evoked field potentials when given 15 or 60 min but not 3 h after LTP induction (Liu, X. G. *et al.*, 1998;Zhang, H. M., *et al.*, 2001). Similarly, blockade of either protein kinase C, calcium-calmodulin-dependent protein kinase II or protein kinase A before or up to 30–60 min after conditioning stimulation abolishes LTP induction. Kinase blockers are, however, ineffective, when applied 3 h after induction. Inhibition of *de novo* protein synthesis in spinal dorsal horn during high frequency stimulation of sciatic nerve selectively blocked late phase of LTP but not its early phase lasting for about 3 h (Hu, N. W. *et al.*, 2003).

5.29.6 Functional Consequences of Long-Term Potentiation in Pain Pathways

A number of studies provide convergent evidence that LTP at spinal synapses of nociceptive Aδ- or C-fibers facilitates downstream processing of pain-related information. This includes action potential firing in superficial and deep dorsal horn neurons (Svendsen, F. *et al.*, 1999; Willis, W. D., 2002; Wallin, J. *et al.*, 2003; Twining, C. M. *et al.*, 2004; Pedersen, L. M. *et al.*, 2005) and pain perception in human subjects (Klein, T. *et al.*, 2004). Induction protocols signal transduction pathways and pharmacology of LTP and facilitation of C-fiber-evoked discharges largely overlap, which is in line with the hypothesis that LTP underlies these facilitations. Under some pathological conditions facilitation of C-fiber-evoked action potential discharges is enhanced, for example, when descending pathways are interrupted (Gjerstad, J. *et al.*, 2001) or if a joint is inflamed (Vikman, K. S. *et al.*, 2003). Induction of LTP of A-fiber-evoked field potentials by high frequency conditioning stimulation is facilitated in animals with a loose ligation of sciatic nerve (Miletic, G. and Miletic, V., 2000). One study reported reduced facilitation in animals with spinal nerve ligations (Rygh, L. J. *et al.*, 2000).

5.29.7 Conclusions

Induction protocols signal transduction pathways and pharmacology of LTP and some forms of hyperalgesia are virtually identical, rendering LTP in spinal dorsal horn an attractive cellular model of hyperalgesia.

5.30.1 Introduction

Tissue destruction or inflammation are accompanied by an invasion of immune cells and liberation of numerous mediators. While these mediators contribute to the body's ability to counteract the destruction of tissue integrity, they also elicit pain by activation of specialized primary afferent neurons called nociceptors (reviewed in Julius, D. and Basbaum, A. I., 2001). They are defined as "receptors preferentially sensitive to a noxious stimulus or to a stimulus which would become noxious if prolonged" (definition of the International Association for the Study of Pain, IASP) (Merskey, H. and Bogduk, N., 1994). Trigeminal and dorsal root ganglia (DRG) contain nociceptor cell bodies which give rise to myelinated Aδ and unmyelinated C fibers. Aδ and C fibers transduce and propagate noxious stimuli to the dorsal horn of the spinal cord from where these stimuli are transmitted to the brain. At the level of the spinal cord and at supraspinal sites, various neurotransmitters come into plays which, together with environmental and cognitive factors, contribute to the eventual sensation of pain (Scholz, J. and Woolf, C. J., 2002). Strictly speaking, analgesia is defined as the inhibition of pain in man, while antinociception is defined as the inhibition of behavioral responses to noxious stimuli in animals. Although central mechanisms also play a prominent role, the following chapter will focus on the peripheral injured tissue itself.

5.30.2 Proalgesic Mechanisms

Inflammatory pain is characterized by an increased response to mechanical and heat stimuli, which are normally painful (Merskey, H. and Bogduk, N., 1994). This is called mechanical or thermal hyperalgesia, respectively. After tissue injury, local tissue macrophages and dendritic cells are activated. The inflammatory response is amplified by migration of leukocytes into the inflamed tissue, by production of inflammatory mediators as well as tissue acidification. Several agents are used experimentally to induce nonspecific inflammation in experimental animals. The most widely used are carrageenan and complete Freund's adjuvant (CFA) injected into the hindpaw of rodents. Carrageenan is used for short-term inflammation, while CFA is used to model longer time courses of tissue injury. Less frequently used agents include lipopolysaccharide, zymosan injection, or peritoneal inflammation using acetic acid or glycogen.

Neuropathic pain can arise following injury of peripheral nerves, when damaged or neighboring undamaged nerve fibers are sensitized or fire ectopically. It is also characterized by mechanical and thermal hyperalgesia. In addition, animals with neuropathy are sensitive to stimuli that do not evoke pain behavior under normal conditions, e.g., to touch, cooling, or warming. This is called allodynia (Merskey, H. and Bogduk, N., 1994). The most common models of neuropathic pain are tight ligation of spinal nerves and tight or loose ligation of the sciatic nerve. These models differ in the degree of neuronal damage but all resemble human neuropathy resulting from trauma-induced injury of peripheral nerves (e.g. entrapment, chronic nerve compression) (Bennet, G. J., 1994).

In the following section the effects of different mediators including cytokines, chemokines, nerve growth factor (NGF), and bradykinin are discussed in three aspects: injection of the mediator into non-inflamed tissue, blocking the mediator in models of inflammatory pain, and the role of the mediator in neuropathic pain.

5.30.2.1 Proinflammatory Cytokines

Cytokines are small proteins produced in the inflamed tissue as well as in lymphoid organs with stimulatory or inhibitory properties on immune function. Cytokines act through high-affinity receptors. Among the many different cytokines, the type I cytokines have a similar four α helical bundle structure. Their receptors correspondingly share characteristic features that have led to their description as the cytokine receptor superfamily, or type I cytokine receptors. Cytokine receptors in general are characterized by low abundance and a multisubunit structure yielding low- and high-affinity receptor forms. They are integral membrane glycoproteins with the N-terminal outside and a single membrane-spanning domain. Unlike growth factors that contain an instrinsic tyrosine kinase in their cytoplasmic domain, cytokine receptors induce tyrosine phosphorylation via additional molecules. Multiple signaling pathways/molecules have been observed for various cytokines. Collectively, these include the Jak-STAT pathway, the Ras–mitogen-activated protein (MAP) kinase pathway, Src and ZAP70 and related proteins, phosphatidylinositol 3-kinase

(PI3K), insulin receptor substrates 1 and 2 (IRS-1 and IRS-2), and phosphatases.

Cytokines are produced on demand and travel only over short distances. *In vivo* concentrations are in the range of a few picograms to nanograms per milliliter. Cytokines are pleiotropic and redundant, they influence mostly immune cells and the inflammatory response. Recently, however, cytokines have been shown to link the immune system and the nervous system and they seem to modulate pain and hyperalgesia.

5.30.2.1.1 Tumor necrosis factor-α

The tumor necrosis factor (TNF) recptor superfamily is comprised of at least 19 genes encoding 20 type II (i.e., intracellular N-terminus, extracellular C-terminus) transmembrane proteins. Included are several well-known ligands such as TNF-α, TNF-β (lymphotoxin-α, LT-α), Fas ligand, and CD40 ligand, as well as an increasing number of newly described mediators. TNF-α is the prototypic proinflammatory cytokine due to its role in initiating a cascade of cytokines and growth factors in the inflammatory response. Intraplantar injection of TNF-α into non-inflamed paws produced a short-lived dose-dependent mechanical hyperalgesia in rats (Cunha, F. Q. *et al.*, 1992). TNF-α seems to have indirect as well as direct hyperalgesic properties. Indirect action is supported by the following evidence: inhibitors of prostaglandin synthesis via cyclooxygenase (COX) inhibitors, and antagonists of adrenergic receptors can attenuate TNF-α-induced hyperalgesia in rats. In mice, TNF-α action is only dependent on the prostaglandin pathway (Cunha, T. M. *et al.*, 2005). Interestingly, the actions of TNF-α seem to be longer lasting if TNF-α is administered repetitively. Such treatment resulted in hyperalgesia lasting up to 30 days after cessation of the daily TNF-α injections in rats (Sachs, D. *et al.*, 2002). TNF-α-induced hyperalgesia in this study was again dependent on release of prostaglandins, as well as sympathetic amines, because blockade of either reduced hyperalgesia. Other groups have demonstrated a role of NGF in TNF-α-induced hyperalgesia. Pretreatment of rats with anti-NGF antiserum significantly attenuated TNF-α-induced mechanical and thermal hyperalgesia (Woolf, C. J. *et al.*, 1997). A direct action on nociceptors was postulated in electrophysiological studies (Sorkin, L. S. *et al.*, 1997; Junger, H. and Sorkin, L. S., 2000). TNF-α applied onto the sciatic nerve or injected subcutaneously into normal paws produced aberrant electrophysiological activity and dose dependently sensitized nociceptors to mechanical stimuli. This effect was restricted to Aδ and C fibers and no effect was seen in Aβ mechanoreceptive fibers. Interestingly, however, higher doses of TNF-α produced lower responses (U-shaped dose–response). The authors postulated that this was related to TNF-α-induced release of anti-inflammatory cytokines (Sorkin, L. S. *et al.*, 1997; Junger, H. and Sorkin, L. S., 2000).

TNF-α exerts its effects through two known receptors, TNFR1 and TNFR2. Expression of both was evaluated in DRG from rats (Li, Y. *et al.*, 2004): TNFR1 mRNA was expressed in virtually all neurons and in nonneuronal cells with increased levels in models of peripheral inflammation. TNFR2 was exclusively expressed and regulated in nonneuronal cells. *In situ* hybridization revealed varying levels of TNFR1 mRNA in virtually all DRG neurons including putative nociceptive neurons coding for calcitonin gene-related peptide, substance P, or vanilloid receptor 1 (transient receptor potential vanilloid 1; TRPV1). Similarly, expression of TNFR1 and TNFR2 protein was seen in rat DRG neurons and their axons and increased in models of neuropathic pain (Shubayev, V. I. and Myers, R. R., 2001; Schäfers, M. *et al.*, 2003c). In contrast, TNFR1 is not expressed in DRG neurons from normal mice but is seen in mice with nerve injury (Ohtori, S. *et al.*, 2004). TNFR localization on peripheral endings has not been examined but seems likely because of expression in DRG and its presence in axons.

Some studies are available regarding the role of endogenous TNF-α in inflammatory hyperalgesia. In one study, antisera against TNF-α could completely block hyperalgesia induced by intraplantar carrageenan injection (Cunha, F. Q. *et al.*, 1992). Similar results are seen in lipopolysaccharide-induced inflammation (Ferreira, S. H. *et al.*, 1993). A third study examined TNF-α in CFA-induced hindpaw inflammation (Woolf, C. J. *et al.*, 1997). Here, a single injection of anti-TNF-α serum before CFA application significantly delayed the onset of the resultant inflammatory hyperalgesia and reduced interleukin (IL)-1β but not NGF levels measured 24 h later. A role for TNF-α in inflammatory pain has also been confirmed in mice using TNFR1 knockout mice (Cunha, T. M. *et al.*, 2005). The intensity of hyperalgesia after intraplantar carrageenan injection was significantly lower in these animals. Therefore, TNF-α seems to be an endogenous mediator in inflammatory pain in mice and in rats. Monocytes and tissue macrophages are the primary

sources for TNF-α synthesis. TNF-α synthesis is stimulated by a wide variety of agents. In macrophages, it is induced by biological, chemical, and physical stimuli such as viruses, bacterial and parasitic products, tumor cells, complement, cytokines, ischemia, trauma, and irradiation (Figure 1) (Cunha, F. Q. and Ferreira, S. H., 2003; Cunha, T. M. *et al.*, 2005). In peripheral tissues of rats, TNF-α activity is followed by increases in IL-6 and IL-8, and IL-6 is followed by IL-1β and then by NGF. All of these finally mediate their effects through prostaglandins or sympathetic amines. This cascade is also seen with few modifications in mice (Cunha, T. M. *et al.*, 2005).

The role of TNF-α has also been studied in neuropathic pain. TNF-α mRNA was upregulated in the sciatic nerve at 2 weeks after its loose ligation (a chronic constriction injury model) (Okamoto, K. *et al.*, 2001). Also, TNF-α protein was detected in inflammatory cells accumulating at the ligated sciatic nerve (Cui, J. G. *et al.*, 2000; Schäfers, M. *et al.*, 2003a). Treatment of animals with neuropathic injury using anti-TNF-α antibodies and especially with the combination of anti-TNF-α and anti-IL-1β antibodies significantly reduced signs of neuropathic pain (Schäfers, M. *et al.*, 2001). In another model, treatment starting 2 days before spinal nerve ligation with the TNF-α receptor antagonist etanercept attenuated mechanical allodynia (Schäfers, M. *et al.*, 2003d). *In vivo* studies have recently been substantiated by electrophysiological studies. *In vitro* perfusion of DRG cells with TNF-α elicits neuronal discharges in Aδ and C fibers, which are markedly higher and longer lasting after nerve injury (Schäfers, M. *et al.*, 2003b). This demonstrates an increased sensitivity of injured neurons to TNF-α. TNF-α-induced hyperalgesia in this model is mediated via TNFR1 (Schäfers, M. *et al.*, 2003c). Downstream effectors of TNF-α include the p38 MAP kinase pathway. Intrathecal infusion of a p38 inhibitor reduced neuropathic pain if it was started before but not 7 days after spinal nerve ligation. Cessation of therapy resulted in increased allodynia.

In summary, TNF-α has hyperalgesic properties if injected exogenously. It also has endogenous hyperalgesic actions in inflammatory and neuropathic pain. The effect seems to be mediated in part indirectly via prostaglandins and sympathetic amines. Recent data also suggest direct sensitizing effects on sensory neurons.

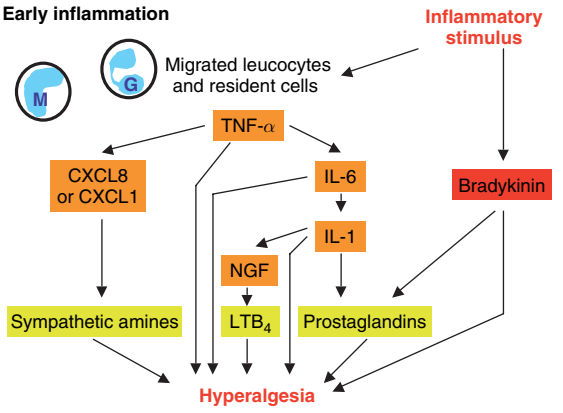

Figure 1 Hyperalgesic mechanisms in early inflammation. An inflammatory agent stimulates the migration of leukocytes, e.g., granulocytes (G) and monocytes (M), into the inflamed tissue. In the tissue, these leukocytes as well as resident cells initiate a cascade of cytokines including tumor necrosis factor-α (TNF-α) and interleukins (ILs), chemokines (CXCL8, CXCL1), nerve growth factor (NGF), bradykinin, and secondary mediators like sympathetic amines, leukotriene B_4 (LTB_4), and prostaglandins culminating in hyperalgesia. TNF-α, IL-6, IL-1, and bradykinin can also have direct hyperalgesic effects on nociceptors.

5.30.2.1.2 *Interleukin-1β*

IL-1 and its family members are primarily proinflammatory cytokines. They can stimulate the expression of genes associated with inflammation and autoimmune diseases. The most salient and relevant properties of IL-1 in inflammation are the initiation of COX, type 2 phospholipase A, and inducible nitric oxide synthase. Hyperalgesic effects of IL-1 have first been demonstrated by injection into hindpaws of rats without inflammation or nerve injury (Ferreira, S. H. *et al.*, 1988): in contrast to IL-1α, IL-1β is able to sensitize nociceptors. Several mechanisms have been proposed to mediate this indirect action, including prostaglandins, nitric oxide, NGF, and bradykinin. The hyperalgesic effect of IL-1β is blocked by treatment with indomethacin, a nonselective COX inhibitor reducing the formation of prostaglandins (Figure 1) (Ferreira, S. H. *et al.*, 1988). In mice, IL-1β also induces prostaglandin formation mediating hyperalgesia (Cunha, T. M. *et al.*, 2005). Injection of IL-1β into normal tissue induces thermal hyperalgesia and the production of NGF. The thermal hyperalgesia but not the NGF production can be prevented by pretreatment with recombinant IL-1 receptor antagonist (IL-1ra). There is also evidence of a direct action of IL-1β on nociceptors: intraplantar injection of IL-1β potentiates action potentials in rat DRG neurons in response to thermal or mechanical stimuli, and a decrease of the mechanical threshold for nerve firing was observed

after local injection of IL-1β (Fukuoka, H. *et al.*, 1994). In the *in vitro* skin–nerve preparation brief exposure to IL-1β facilitates the heat-induced release of calcitonin gene-related peptide (a pronociceptive mediator) from peptidergic sensory neurons (Opree, A. and Kress, M., 2000). This was confirmed by a follow-up study (Obreja, O. *et al.* 2002a). IL-1 potentiated heat-activated inward currents and shifted the activation threshold towards lower temperature without altering intracellular calcium currents.

Intracellular mediators of these effects included protein tyrosine kinases and protein kinase C. One of the IL-1 receptors subtypes, the IL-1RI, was expressed in DRG cells as shown by polymerase chain reaction and *in situ* hybridization. The authors propose that recruitment of tyrosine kinases and downstream activation of protein kinase C phosphorylate TRPV1 to cause heat hyperalgesia. Both mRNA and IL-1RI protein are found in DRG neurons and glial cells (Li, M. *et al.*, 2005) of rats with and without paw inflammation. However IL-1RI localization has not been shown on peripheral nerve terminals. Using autoradiography, we did not detect IL-1 binding on nerves in either inflamed or noninflamed paws, but on immune cells in inflamed paws (Mousa, S. A. *et al.*, 1996). Therefore, IL-1 receptor expression in the periphery requires further studies.

IL-1β also has an endogenous hyperalgesic role in inflammatory as well as in neuropathic pain. In hindpaw inflammation induced by carrageenan or lipopolysaccharide IL-1ra can reduce, by not completely block, hyperalgesia in rats and in mice (Ferreira, S. H. *et al.*, 1993; Cunha, J. M. *et al.*, 2000; Cunha, T. M. *et al.*, 2005). The same effect can be seen in CFA-induced hindpaw inflammation or in mice after intraperitoneal injection of acetic acid (Safieh-Garabedian, B. *et al.*, 1995; Cunha, J. M. *et al.*, 2000). In CFA-induced inflammation, the authors propose that the effect is mediated by NGF, because treatment with IL-1ra also reduced the local production of NGF (Safieh-Garabedian, B. *et al.*, 1995). Interestingly, our group has shown analgesic effects of IL-1β via release of opioid peptides from immune cells in CFA-induced inflammation (see Analgesic Effects of Corticotropin Releasing Factor, Interleukin-1β, and Noradreline for discussion).

In neuropathic pain models, the role of IL-1 has not been thoroughly examined. Expression of IL-1β is seen in inflammatory cells accumulating at the sciatic nerve in ligation and inflammatory models of neuropathy as assesed by immunohistochemistry and by polymerase chain reaction (Gazda, L. S. *et al.*, 2001; Okamoto, K. *et al.*, 2001). Blocking of IL-1R in mice with chronic constriction injury reduces thermal hyperalgesia, mechanical allodynia, and also immunoreactivity for TNF-α (Sommer, C. *et al.*, 1999). However, the mechanisms remain unclear. So far, no study has demonstrated IL-1R expression in neuropathy. In summary, IL-1β seems to have hyperalgesic actions in different models of pain. The mechanism – direct or indirect – still needs to be clarified.

5.30.2.1.3 Interleukin-6

IL-6 is a one of the major proinflammatory cytokines. Its level is below detection under physiological conditions but is rapidly and strongly upregulated in early inflammation and can be detected early in the serum. Intraplantar injection of IL-6 induces hyperalgesia in normal rats (Poole, S. *et al.*, 1995). An indirect mechanism of this effect is supported by data showing inhibition of IL-6-induced hyperalgesia when animals are treated with COX blockers (Cunha, F. Q. *et al.*, 1992) (Figure 1). However, so far it is not known which cells and receptors are involved.

Direct effects have been proposed by other groups: In the rat *in vitro* skin–nerve preparation basal and heat-evoked release of calcitonin gene-related peptide from nociceptors was measured. IL-6 did not induce heat sensitization, when applied alone, but was effective in the presence of soluble IL-6 receptor (sIL-6R) (Opree, A. and Kress, M., 2000). sIL-6R is needed for cells that express only the signaling receptor unit gp130. The complex of sIL-6R and IL-6 can then induce a signal to activate cells. This so-called *trans*-signaling expands the spectrum of cells responsive to IL-6 to include neurons. IL-6, in combination with its soluble receptor, can sensitize nociceptors to heat, providing evidence for the constitutive expression of gp130, but not of the IL-6-membrane-bound (specific) receptor, in nociceptors (Obreja, O. *et al.*, 2002b). Hyper-IL-6 (HIL-6), a fusion protein of IL-6 and sIL-6R, was designed to mimic the effects of the IL-6–sIL-6R complex. *In vitro* exposure of DRG neurons to HIL-6 potentiated heat-activated inward currents and shifted the activation thresholds towards lower temperatures without affecting intracellular calcium levels (Obreja, O. *et al.*, 2005). This effect was reduced by a Janus tyrosine kinase inhibitor, a selective protein kinase C inhibitor as well as a selective blocker of the protein kinase C delta isoform, but not by the COX inhibitor indomethacin. *In situ* hybridization and reverse transcription-polymerase chain

reaction revealed expression of the signal-transducing beta subunit of gp130 in neuronal somata but not in satellite cells in DRG from normal rats (Gadient, R. A. and Otten, U., 1996; Obreja, O. *et al.*, 2005). These data suggest a direct activation of sensory neurons by IL-6–sIL-6R.

As seen for IL-1β and TNF-α, endogenous IL-6 is also important for the development of hyperalgesia: Antisera neutralizing IL-6 inhibited lipopolysaccharide-induced hyperalgesia in rats (Ferreira, S. H. *et al.*, 1993). IL-6 knockout mice were shown to have reduced thermal and mechanical hyperalgesia after injection of carrageenan into the hindpaw (Xu, X. J. *et al.*, 1997). In this study, however, IL-6 knockout mice without inflammation displayed baseline hyperalgesia, which could not be explained by the authors.

In neuropathic mice, IL-6 mRNA levels were upregulated in DRG and correlated well with the development of nerve injury-induced thermal hyperalgesia and mechanical allodynia (Murphy, P. G. *et al.*, 1999). IL-6 knockout mice had reduced thermal and mechanical hyperalgesia in the chronic constriction injury model. In summary, IL-6 belongs to the group of proinflammatory hyperalgesic cytokines with direct as well as indirect effects on neurons, similar to IL-1β and TNF-α.

5.30.2.1.4 Interleukin-18

IL-18 is a member of the IL-1 ligand superfamily and is expressed in various cell types including macrophages and dendritic cells. Its biological functions include stimulation of activated T cells and enhancement of natural killer cell lytic activity. Furthermore, IL-18 activates and attracts neutrophils by inducing the production of TNF-α and subsequently leukotriene B_4. Injection of IL-18 into normal paws caused time and dose-dependent mechanical hyperalgesia (Verri, W. A., Jr. *et al.*, 2004) Interestingly, only morphine and dexamethasone blocked IL-18-induced hyperalgesia, whereas blockade of the prostaglandin or sympathetic pathway had no effect. In fact, the hyperalgesia elicited by IL-18 seems to be mediated via endothelin receptors, because it was abolished by blockage of endothelin receptor B (Verri, W. A., Jr. *et al.*, 2004).

5.30.2.2 Chemokines

Chemokines (CC and CXC) are chemotatic mediators produced in inflamed tissue. They control trafficking of leukocytes under physiological and inflammatory conditions, angiogenesis, and wound healing. They can be divided into subfamilies based on their structural motifs (the position of cysteine residues located near the N-terminus of the protein: CC, CXC, and CX_3C). Chemokines bind to a group of chemokine receptors (CCR, CXCR, and CX_3CR; seven transmembrane-spanning G_i protein-coupled receptors) expressed on leukocytes. Although each receptor subtype typically binds multiple chemokines, the specificity is defined by a chemokine subfamily. Recently, chemokines and their receptors have been detected on cells in the central and peripheral nervous system.

Several observations indicate a role of chemokines in hyperalgesia. Chemokine receptors such as CXCR4 and CCR4 are expressed on subpopulations of DRG neurons and their corresponding ligands can induce calcium influx (Oh, S. B. *et al.*, 2001). However, in neonates the percentage of neurons responding to chemokine stimulation was significantly lower than the percentage responding to bradykinin or capsaicin. Direct intraplantar injection of some chemokines (CCL5, CXCL12, and CCL22) induces hyperalgesia in normal animals (Oh, S. B. *et al.*, 2001). In addition, some chemokines (human CXCL8 (IL-8) or rat CXCL1 (KC keratinocyte-derived chemokine)) can indirectly cause hyperalgesia through release of sympathetic amines when applied subcutaneously into the hindpaw (Lorenzetti, B. B. *et al.*, 2002; Cunha, F. Q. and Ferreira, S. H., 2003). Hyperalgesic effects of CXCL1 were further examined in mice (Cunha, T. M. *et al.*, 2005). Intraplantar injection of a small dose of CXCL1 induced hyperalgesia with a peak between 3 and 5 h returning to normal after 24 h. Pretreatment of mice with indomethacin, a COX inhibitor, or guanethidine, a blocker of sympathetic amines, reduced the hyperalgesia. An almost complete blockade was achieved if both agents were combined. Interestingly, CXCL1-induced hyperalgesia could also be inhibited by IL-1ra but no change was seen in TNFR1 knockout mice. Therefore, IL-1β seems to be downstream of CXCL1, whereas TNF-α is upstream. In contrast, our own unpublished data suggest that intraplantar injection of CXCL1 as well as CXCL2/3 (MIP-2 macrophage inflammatory protein) in normal rats does not evoke thermal or mechanical hyperalgesia for up to 12 h postinjection despite significant recruitment of granulocytes. Differences could be explained by the doses or the behavioral test used (see below). Doses producing maximal chemokine-induced granulocyte recruitment do not induce hyperalgesia in our model Rittner, H. L., *et al.* 2006.

In a recent study, a connection between chemokines and TRPV1 was shown (Zhang, N. *et al.*, 2005). CCL3 (macrophage inflammatory protein 1α) that binds to CCR1 was tested *in vitro* and *in vivo*. Activation of CCR1 resulted in increases in TRPV1-mediated Ca^{2+} influx and increased sensitivity of TRPV1 to its ligand capsaicin. *In vivo* the latency in the mouse hot plate test was reduced for up to 45 min after a local injection of CCL3. Thus, CCL3 seems to be capable of enhancing the sensitivity of TRPV1, possibly through a G protein-dependent signaling pathway.

The endogenous role of chemokines was studied in rats and mice in carrageenan-induced hindpaw inflammation. In studies by Ferreira *et al.*, human CXCL8 and rat CXCL1 were shown to contribute to carrageenan-induced hyperalgesia in rats (Cunha, F. Q. *et al.*, 1991; Lorenzetti, B. B. *et al.*, 2002; Sachs, D. *et al.*, 2002). Similarly, injection of carrageenan elicited hyperalgesia, which could be reduced by pretreatment with anti-CXCL1 antibodies in mice (Cunha, T. M. *et al.*, 2005). Therefore, part of the hyperalgesia seen in carrageenan inflammation is dependent directly or indirectly on certain chemokines. However, our own studies in CFA-induced inflammation suggest an additional role of chemokines in counteracting inflammatory pain. In this model, concomitant injection of CXCL2/3 and CFA induced a threefold increase in the number of neutrophils in the inflamed paw after 2 h, while mechanical and thermal hyperalgesia was not changed (Brack, A. *et al.*, 2004d). Furthermore, inhibition of CXCL1 and CXCL2/3 in inflamed paws had no effect on mechanical hyperalgesia despite significant reduction of the number of infiltrating neutrophils after 2 h (Brack, A. *et al.*, 2004c) (see also Analgesic Effects of Corticotropin Releasing Factor, Interleukin-1β, and Noradreline and Endogenous Opoid Analgesia). The differences between our studies and those by Cunha *et al.*, might be related to the model of inflammation (CFA versus carrageenan) or to the type of behavioral test used. While we determined the amount of mechanical pressure required for the rat to withdraw its paw (modified Randall–Selitto method), Cunha *et al.*, used a substantially more painful stimulus that induced sympathetic activation with a freezing reaction and apnea.

In neuropathic pain the role of chemokines has not been thoroughly examined. Disruption of the gene for CCR2 prevented mechanical allodynia in the chronic constriction injury model (Abbadie, C. *et al.*, 2003). CCR2, activated by CCL2 (monocyte chemotrattractant protein-1), is responsible for attracting monocytes into inflamed tissue. Therefore the authors conclude that the decreased number of monocytes is responsible for the reduced pain in this model. In summary, the contribution of chemokines to hyperalgesia may depend on their type, the model of pain, the time frame and the dose of chemokine used. Some of the indirect effects are mediated by the ability of chemokines to attract monocytes.

5.30.2.3 Nerve Growth Factor

NGF belongs to the family of neurotrophic proteins, together with brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), NT-4/5, and NT-6. NGF governs the innervation of target tissues during development and plays an important role in neuronal survival and maintenance of connectivity. Besides its action on neurons, NGF also has immunomodulatory effects in different inflammatory diseases including asthma, arthritis, and psoriasis. NGF is constitutively expressed in keratinocytes in normal skin. However, many cells including all subtypes of leukocytes as well as sensory neurons can express NGF in inflammation (Vega, J. A. *et al.*, 2003). After binding to its high-affinity receptor tyrosine receptor kinase A (trkA) on peripheral terminals of sensory neurons, NGF is internalized and retrogradely transported to the somata in the DRG. NGF is a potent regulator of gene expression of neuropeptides like calcitonin gene-related peptide and substance P, of receptors like TRPV1 and of ion channels like tetrodotoxin (TTX)-resistant sodium channels. The role of endogenous NGF has mostly been examined using proteins that block the bioactivity of NGF because deletion of NGF or trkA in mice is lethal within the first week of life.

Injection of NGF into the normal rat paw induces a long-lasting thermal as well as mechanical hyperalgesia (Lewin, G. R. *et al.*, 1994). These effects seem to be in part dependent on mast cells and on a central component involving *N*-methyl-D-aspartate (NMDA) receptors. Nociceptor sensitization was also observed *in vitro* in a skin–nerve preparation (Rueff, A. and Mendell, L. M., 1996). Infusion of trkA–IgG into the noninflamed rat paw to block local NGF diminished thermal hyperalgesia and decreased calcitonin gene-related peptide content in DRG neurons (McMahon, S. B. *et al.*, 1995). The detection of sensitizing properties of NGF has been corroborated by the analysis of transgenic mice overexpressing NGF in the epidermis (Stucky, C. L. *et al.*, 1999). These animals developed hyperalgesia without any signs of inflammation of the

skin. In electrophysiological studies unmyelinated nociceptors responded with a fourfold intensity to heat stimuli in comparison to wild-type mice. Moreover, almost every C fiber responded to heat in NGF overexpressing animals in contrast to only half of the C fibers in wild-type animals. No enhanced response to mechanical stimuli was seen. Together, this provides supporting evidence for the heat-sensitizing property of NGF. Importantly, endogenous NGF seems to be responsible for maintenance of the sensitivity of nociceptors as application of trkA–IgG fusion molecule to the innervation territory of the cutaneous saphenous nerve resulted in a reduction of innervation density of the epidermis and of the percentage of neurons responding to heat or bradykinin (Bennett, D. L. *et al.*, 1998).

Blocking of NGF by trkA–IgG in carrageenan-induced inflammation prevents the development of thermal hyperalgesia and the sensitization of nociceptors despite normal development of inflammation as measured by tissue edema (McMahon, S. B. *et al.*, 1995; Koltzenburg, M. *et al.*, 1999). Similarly, injection of anti-NGF antibodies blocks the development of thermal hyperalgesia in CFA-induced inflammation (Lewin, G. R. *et al.*, 1994). Thus, NGF seems to be part of the inflammatory cascade involving initially inflammatory cytokines like IL-1β and TNF-α and subsequently NGF (Figure 1) (Cunha, T. M. *et al.*, 2005).

Neuropathic pain is also influenced by NGF; however, the data seem to be controversial. Treatment with anti-NGF in the chronic constriction injury model reduced hyperalgesia but the effect showed a delayed onset, short duration, and dependency on the dosage (Ro, L. S. *et al.*, 1999). In a recent paper the role of NGF and glial cell-line-derived neurotrophic factor (GDNF) on nociceptor function was examined (Zwick, M. *et al.*, 2003). Two lines of transgenic mice that contained an increased number of either NGF- or GDNF-dependent neurons were used. These mice were tested in a model of inflammatory pain (CFA) and neuropathic pain (spinal nerve ligation model). Contrary to expectations, neither line of transgenic mice became more hyperalgesic following induction of persistent pain. In fact, NGF-overexpressing mice recovered more rapidly from initial inflammatory hyperalgesia and became hypoalgesic despite extensive paw swelling in the inflammatory model. In the neuropathic model, only wild-type mice became hyperalgesic. mRNA expression of opioid receptors, NMDA receptors, metabolic glutamate receptor, sodium channels and vanilloid receptors showed marked differences in DRG neurons but not in the spinal cord between wild-type and NGF- or GDNF-overexpressing animals. This suggested that the somatosensory system is capable of producing normal pain behavior despite significant modification of nociceptors.

NGF blockade seems to produce analgesia also in other pain states. In a model of bone cancer pain, osteosarcoma tumor cells are injected into the intramedullary space of the mouse femur. In a recent study, the authors focused on a novel NGF-sequestering antibody and demonstrated that two administrations produce a profound reduction in both ongoing and movement-evoked bone cancer pain-related behaviors that was greater than that achieved with acute administration of 10 or 30 mg kg^{-1} of morphine (Sevcik, M. A. *et al.*, 2005). In summary, neutralization of NGF produces analgesia in most pain models studied.

5.30.2.4 Other Mediators: Bradykinin

Bradykinin is a nonapeptide generated from high-molecular-weight kininogen through cleavage by kallikrein under inflammatory conditions in plasma. It is also released from mast cells during asthma attacks and within the gut as a gastrointestinal vasodilator. Bradykinin is rapidly generated after tissue injury and seems to modulate most of the events observed during the inflammatory process including vasodilatation, increase of vascular permeability, plasma extravasation, and cell migration (reviewed in Calixto, J. B. *et al.*, 2000). It is also one of the most potent endogenous proalgesic mediators (Ferreira, S. H. *et al.*, 1993). It directly activates bradykinin receptors on primary afferent neurons or sensitizes nociceptors indirectly through release of prostaglandins, nitric oxide, neurokinins, calcitonin gene-related peptide, cytokines, and histamine (Figure 1), or via alterations of vanilloid receptor channel gating (Chuang, H. H. *et al.*, 2001). In fact, lipopolysaccharide- or carrageenan-induced inflammation triggers the TNF-α-driven cytokine cascade via the release of bradykinin (references in Cunha, F. Q. and Ferreira, S. H., 2003). Bradykinin is released at the beginning of the inflammation because delayed treatment with bradykinin receptor antagonists 2 h after injection of lipopolysaccharide or carrageenan has no effect on hyperalgesia or inflammation.

Bradykinin also plays a role in neuropathic pain. Ablation of the gene for the bradykinin receptor 1 resulted in a significant reduction of mechanical allodynia and thermal hyperalgesia in early stages of

nerve injury (Ferreira, J. *et al.*, 2005). Furthermore, systemic treatment with the bradykinin receptor 1-selective antagonist des-Arg9-[Leu8]-bradykinin reduced the established mechanical allodynia observed 7–28 days after nerve lesion in wild-type mice. Nonpeptidic orally active bradykinin receptor 1 and 2 antagonists are currently being developed as peripheral analgesics (Sawynok, J., 2003; Marceau, F. and Regoli, D., 2004).

5.30.2.5 Clinical Implications and Perspectives

A myriad of peripheral mediators is involved in inflammatory as well as neuropathic pain. The most frequently used pain medications are selective or nonselective inhibitors of COX. These nonsteroidal anti-inflammatory drugs inhibit the common final pathway of most proalgesic compounds, the production of prostaglandins. However, these drugs have serious side effects such as gastrointestinal ulcer formation, bleeding and/or, thromboembolic events. Because of the multitude of proinflammatory and proalgesic mediators the development of new analgesics is difficult. Inhibiting one pathway may still leave other mediators available. On the other hand, cytokine antagonists such as the TNF-α receptor antagonist etanercept have been developed for treatment of autoimmune disease like rheumatoid arthritis and have been shown to produce analgesia in patients (Sommer, C. *et al.*, 2001). Despite the almost innumerable number of mediators new treatments are under current investigation including, e.g., the blockade of the bradykinin system (Sawynok, J., 2003; Marceau, F. and Regoli, D., 2004). The development of peripherally acting drugs would have advantages such as the avoidance of central side effects. For example, the localized (e.g., topical) administration of drugs can potentially optimize drug concentrations at the site of injury without systemically active drug levels and fewer adverse systemic effects, fewer drug interactions, and no need to titrate doses into a therapeutic range compared with systemic administration.

5.30.3 Analgesic Mechanisms

Leukocytes are the source not only of hyperalgesic mediators but also of antinociceptive mediators. The best-characterized and clinically tested compounds are the endogenous opioid peptides. Other analgesic mediators include anti-inflammatory cytokines, somatostatin (somatotropin release inhibiting factor; SRIF), and the endocannabinoids.

5.30.3.1 Anti-Inflammatory Cytokines

In later stages of inflammation cytokines are produced, which limit inflammation and counteract hyperalgesia (references in Cunha, F. Q. and Ferreira, S. H., 2003). For example, IL-4, IL-10, IL-13, and IL-1ra can produce analgesia (Figure 2) (Cunha, F. Q. *et al.*, 1999; Cunha, J. M. *et al.*, 2000; Cunha, F. Q. and Ferreira, S. H., 2003). IL-4 and IL-13 are produced by Th_2 lymphocytes and mast cells and suppress the production of proinflammatory mediators such as IL-1, TNF-α, interferon-γ, and CXCL8. In addition, inhibition of COX-2 is observed. IL-10 is a product of T-lymphocytes and monocytes and inhibits the production of Th_1 proinflammatory cytokines including IL-1, IL-6, IL-8, and TNF-α. Besides, it upregulates IL-1ra. These effects are also seen in models of pain. Pretreatment with IL-4, IL-10, and IL-13 dose dependently blocked hyperalgesia induced by carrageenan, bradykinin, and TNF-α but did not affect hyperalgesia induced by CXCL8 and prostaglandins. Furthermore, the endogenous role of anti-inflammatory cytokines to limit hyperalgesia was demonstrated by application of antisera against IL-4, IL-10, and IL-13. They potentiated hyperalgesia induced by carrageenan, bradykinin,

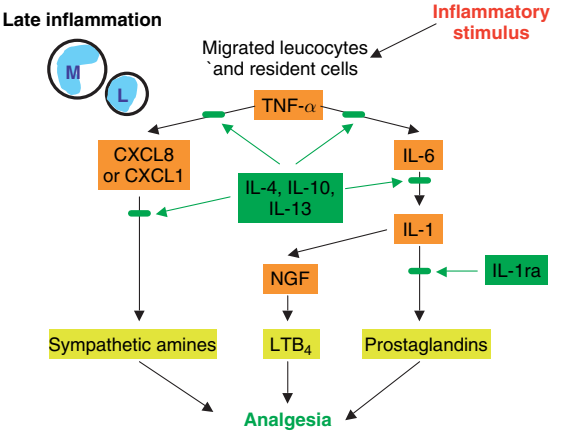

Figure 2 Analgesic cytokines in late inflammation. During ongoing inflammation leukocytes, e.g., lymphocytes (L) and monocytes/macrophages (M), start to produce anti-inflammatory cytokines like interleukin-4 (IL-4), IL-10, IL-13, and IL-1 receptor antagonist (IL-1ra). These cytokines inhibit the proinflammatory cytokines such as TNF-α, IL-1, and IL-6, and block the cascade.

and TNF-α. This effect was not seen in athymic and mast-cell-depleted rats. Thus, it seems that endogenous sources of IL-4 and IL-13 are mast cells and lymphocytes, respectively. Analgesic actions of IL-4, IL-10, and IL-13 are not only seen in paw inflammation but also in models of peritonitis and knee joint incapacitation induced by zymosan. Analgesic properties of anti-inflammatory cytokines are independent of endogenous production of opioid peptides (Vale, M. L. *et al.*, 2003). In summary, during ongoing inflammation analgesic cytokines are produced which counteract the effects of the proinflammatory hyperalgesic cytokines generated in the early stages.

5.30.3.2 Opioid Peptides

5.30.3.2.1 Peripheral opioid receptors

5.30.3.2.1.(i) Localization Opioid peptides are the natural ligands at opioid receptors. Three cDNAs and their genes have been identified, encoding the μ-, δ-, and κ-opioid receptor (MOP, DOP, and KOP), respectively (Kieffer, B. L. and Gaveriaux-Ruff, C., 2002). All three receptors can mediate pain inhibition and they are found throughout the nervous system, including somatic and visceral sensory neurons, spinal cord projection and interneurons, midbrain, and cortex. Recent interest has focused on the identification of opioid receptors on peripheral processes of sensory neurons. The cell bodies of these neurons in DRG express all three mRNAs and receptor proteins (Stein, C. *et al.*, 2001). Opioid receptors are intraaxonally transported into the neuronal processes and are detectable on peripheral sensory nerve terminals in animals and in humans. Colocalization studies confirmed the presence of opioid receptors on neurons expressing substance P and/or calcitonin gene-related peptide in DRG small- and medium-sized neurons and in their central and peripheral terminals (Dado, R. J. *et al.*, 1993; Zhang, X. *et al.*, 1998; Wenk, H. N. and Honda, C. N., 1999; Guan, J. S. *et al.*, 2005). Further, anatomical and electrophysiological studies showed expression of opioid receptors on unmyelinated C and on myelinated Aδ fibers (i.e., nociceptors) (Beland, B. and Fitzgerald, M., 2001; Pare, M. *et al.*, 2001; Suzuki, R. and Dickenson, A. H., 2002) but not on large myelinated Aβ fibers (Arvidsson, U. *et al.*, 1995; Beland, B. and Fitzgerald, M., 2001). However, after nerve injury morphine depressed responses of Aβ fibers (Suzuki, R. and Dickenson, A. H., 2002), and expression δ-receptors on the A$\alpha\beta$ fibers in Meissner corpuscules in glaborus skin has been recently reported (Pare, M. *et al.*, 2001). The binding characteristics (affinity) of peripheral and central opioid receptors are similar but the molecular masses of peripheral and central μ-receptors appear to be different (references in Stein, C. *et al.*, 2003). If these findings are confirmed, a search for selective ligands at such distinct receptors may be warranted.

It has been suggested that opioid receptors are also located on sympathetic postganglionic neuron terminals. However, there are reports arguing against this notion and studies attempting the direct demonstration of opioid receptor mRNA in sympathetic ganglia have produced negative results. In addition, thorough morphological investigations have clearly demonstrated the presence of δ-receptors on unmyelinated primary afferent neurons and the absence of such receptors on postganglionic sympathetic neurons in skin, lip, and cornea. Moreover, chemical sympathectomy with 6-hydroxydopamine does not change the expression of opioid receptors in the DRG or the peripheral analgesic effects of μ-, δ-, and κ-receptor agonists in a model of inflammatory pain. Together, these findings have corroborated the notion that peripheral opioid receptors mediating analgesia are exclusively localized on primary sensory neurons (references in Stein, C. *et al.*, 2001).

Opioid binding sites and the expression of opioid receptor transcripts have also been demonstrated in immune cells. Opioid-mediated modulation of the proliferation of these cells and of their functions (e.g., chemotaxis, superoxide and cytokine production, mast cell degranulation) has been reported. These immunomodulatory actions can be stimulatory as well as inhibitory and have been ascribed to the activation of opioid receptors (Sacerdote, P. *et al.*, 2003; Sharp, B. M., 2003). However, the significance of such effects with regard to pain transmission has not been investigated as yet.

5.30.3.2.1.(ii) Opioid receptor signaling in sensory neurons All three types of opioid receptors mediate the inhibition of high-voltage-activated calcium currents in cultured primary afferent neurons. These effects are transduced by G proteins (G_i and/or G_o) (references in Stein, C. *et al.*, 2001; 2003). Although it is well-known that opioids induce membrane hyperpolarization due to increased potassium currents in central neurons, this could not be detected in DRG neurons so far (Akins, P. T. *et al.*, 1993). Thus, the modulation of calcium channels appears to be the primary mechanism for the inhibitory effects of opioids on peripheral sensory neurons. In addition,

opioids – via inhibition of adenylyl cyclase – suppress TTX-resistant sodium- and nonselective cation currents stimulated by the inflammatory agent prostaglandin E_2 (Ingram, S. L. and Williams, J. T., 1994; Gold, M. S. and Levine, J. D., 1996). Interestingly, TTX-resistant sodium channels are selectively expressed in nociceptors, they are important for impulse initiation and action potential conductance, they mediate spontaneous activity in sensitized nociceptors and they accumulate at the site of injury in damaged nerves leading to ectopic impulse generation (Porreca, F. *et al.*, 1999; Laird, J. M. *et al.*, 2002). The latter observations may explain the notable efficacy of peripheral opioids in inflammatory and neuropathic pain (Stein, C. *et al.*, 2001; 2003). Consistent with their effects on ion channels, opioids attenuate the excitability of peripheral nociceptor terminals, the propagation of action potentials, the release of excitatory proinflammatory neuropeptides (substance P, calcitonin gene-related peptide) from peripheral sensory nerve endings, and vasodilatation evoked by stimulation of C fibers (references in Stein, C. *et al.*, 2001). All of these mechanisms result in analgesia and/or anti-inflammatory actions.

5.30.3.2.1.(iii) Peripheral opioid receptors and inflammation Peripheral opioid analgesic effects are augmented under conditions of tissue injury such as inflammation, neuropathy, or bone damage (Stein, C. *et al.*, 2001; 2003). One underlying mechanism is an increased number (upregulation) of peripheral opioid receptors. In neuronal cell cultures, μ-receptor transcription is upregulated by the cytokine IL-4 through binding of STAT6 transcription factors to the μ-receptor gene promoter (Kraus, J. *et al.*, 2001). In DRG, the synthesis and expression of opioid receptors can be increased by peripheral tissue inflammation (Ji, R. R. *et al.*, 1995; Zöllner, C. *et al.*, 2003). Subsequently, the axonal transport of opioid receptors is greatly enhanced leading to their upregulation and to enhanced agonist efficacy at peripheral nerve terminals (Jeanjean, A. P. *et al.*, 1995; Mousa, S. A. *et al.*, 2001). In addition, the specific milieu (low pH, prostanoid release) of inflamed tissue may increase opioid agonist efficacy by enhanced G protein coupling and by increased neuronal cyclic adenosine monophosphate levels (Selley, D. E. *et al.*, 1993; Ingram, S. L. and Williams, J. T., 1994; Zöllner, C. *et al.*, 2003). Inflammation also leads to an increase in the number of sensory nerve terminals (sprouting) and disrupts the perineurial barrier, thus facilitating the access of opioid agonists to their receptors (Stein, C. *et al.*, 2001; 2003).

5.30.3.2.2 Opioid peptides produced by immune cells

Three families of opioid peptides are well characterized in the central nervous and neuroendocrine systems (Akil, H. *et al.*, 1998). Each family derives from a distinct gene and from one of the three precursor proteins proopiomelanocortin (POMC), proenkephalin (PENK), or prodynorphin, respectively. Appropriate processing yields their respective representative opioid peptides, the endorphins, enkephalins, and dynorphins (Table 1). These peptides exhibit different affinity and selectivity for the three opioid receptors μ (endorphins, enkephalins), δ (enkephalins, endorphins), and κ (dynorphin). Two additional endogenous opioid peptides have been isolated from bovine brain: endomorphin-1 and endomorphin-2 (Table 1). Both peptides are considered highly selective μ-receptor ligands. Their precursors are not known yet. All of these opioid peptides have been detected in immune cells but the POMC and PENK families have been studied most extensively.

5.30.3.2.2.(i) Proopiomelanocortin-derived opioid peptides POMC-related opioid peptides have been found in immune cells of many vertebrates and nonvertebrates (references in Machelska, H. *et al.*, 2002). To determine whether these immune-competent cells actually synthesize POMC rather than simply absorb related peptides from plasma,

Table 1 Structure of endogenous opioid peptides

β-Endorphin	Tyr-Gly-Gly-Phe-Met-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Asn-Ala-Ile-Val-Lys-Asn-Ala-His-Lys-Lys-Gly-Gln-OH
Methionine-enkephalin	Tyr-Gly-Gly-Phe-Met-OH
Leucine-enkephalin	Tyr-Gly-Gly-Phe-Leu-OH
Dynorphin A	Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile-Arg-Pro-Lys-Leu-Lys-Tyr-Asp-Asn-Gln-OH
Endomorphin-1	Tyr-Pro-Trp-Phe-OH
Endomorphin-2	Tyr-Pro-Phe-Phe-OH

mRNA encoding POMC was sought for and demonstrated in many of these studies. The pituitary POMC gene is organized into three exons separated by intervening sequences which are removed during processing following transcription to produce the full-length, 1200-nt transcript. Initially, truncated POMC transcripts were found in leukocytes (references in Machelska, H. *et al.*, 2002). Lyons P. D. and Blalock J. E. (1997) reexamined the question of POMC mRNA expression using novel polymerase chain reaction procedures. With this exacting and sensitive methodology, they found expression of full-length transcripts encoding all three POMC exons in rat mononuclear leukocytes. This POMC transcript is spliced in the same way as the pituitary transcript and contains the sequence for the signal peptide, which is necessary for the correct routing into the regulated secretory pathway. The POMC protein is also proteolytically processed in a way consistent with the pituitary gland (Lyons, P. D. and Blalock, J. E., 1997; Mousa, S. A. *et al.*, 2004). These results unequivocally demonstrate that immune cells can produce full-length POMC transcripts. Apparently, this production is stimulated by various immune and inflammatory mediators (Smith, E. M., 2003).

5.30.3.2.2.(ii) Proenkephalin-derived opioid peptides PENK-derived opioid peptides have also been detected in human and rodent immune cells. Both the mRNA and methionine (Met)-enkephalin protein were detected. Preproenkephalin mRNA was found in T- and B-cells, macrophages, and mast cells. In subpopulations of immune cells this mRNA was shown to be highly homologous to brain PENK mRNA, abundant and apparently translated, as immunoreactive enkephalin is present and/or released. The appropriate enzymes necessary for posttranslational processing of PENK have also been identified in immune cells (references in Machelska, H. *et al.*, 2002).

5.30.3.2.2.(iii) Immune-derived opioid peptides in inflammation Immune-derived opioid peptides apparently play a substantial role in the modulation of inflammatory pain (Machelska, H. *et al.*, 2002; Stein, C. *et al.*, 2003). POMC mRNA and β-endorphin, as well as Met-enkephalin and dynorphin were found in cells derived from lymph nodes, and in leukocytes in the blood and within inflamed tissue in CFA model of inflammatory pain (Cabot, P. J. *et al.*, 1997; 2001; Machelska, H. *et al.*, 2003; Mousa, S. A. *et al.*, 2004). In the pituitary, POMC processing begins as the nascent polypeptide enters the endoplasmic reticulum directed by the signal peptide, and POMC cleavage begins in the *trans*-Golgi network (references in Mousa, S. A. *et al.*, 2004). The POMC prohormone is directed to the regulated secretory pathway at the *trans*-Golgi network by binding to a sorting receptor, membrane-bound carboxypeptidase E. The prohormone convertases PC1 (also called PC1/3) and PC2 cleave POMC within the *trans*-Golgi network. PC1 mediates the initial cleavage into adrenocorticotropic and β-lipotropic hormones. The inactive pro-PC2 is bound to 7B2 (a chaperone-like binding protein) and is transported from the endoplasmic reticulum to later compartments of the secretory pathway, where it matures to active PC2; thereafter, PC2 converts β-lipotropic hormone into β-melanocyte stimulating hormone and β-endorphin (references in Mousa, S. A. *et al.*, 2004). Recently, we detected β-endorphin and POMC alone and colocalized with PC1, PC2, carboxypeptidase E, and 7B2 in leukocytes in the blood and within inflamed paw tissue (Mousa, S. A. *et al.*, 2004). This demonstrates that immune cells express the entire machinery required for POMC processing into functionally active β-endorphin.

In this CFA model, mRNAs encoding POMC and PENK and the corresponding opioid peptides β-endorphin and Met-enkephalin are abundant in cells of inflamed but not in noninflamed tissue (Przewlocki, R. *et al.*, 1992). Histomorphological procedures and flow cytometry have identified the opioid-containing cells as T- and B-lymphocytes, granulocytes, and monocytes/macrophages (Przewlocki, R. *et al.*, 1992; Rittner, H. L. *et al.*, 2001). Also, it was shown that β-endorphin is present in activated/memory T-cells within inflamed tissue (Cabot, P. J. *et al.*, 1997; Mousa, S. A. *et al.*, 2001). Thus, opioid peptides are processed and present both in circulating and inflammatory cells infiltrating injured tissue.

5.30.3.2.3 Migration of opioid-containing immune cells to inflamed tissue

The recruitment of leukocytes from the circulation into areas of inflammation begins with the attachment of these cells to vascular endothelium, followed by their transmigration into the tissue. This is mediated by specific cell adhesion and chemoattractant/activator molecules. Leukocytes are recruited from the circulation by a well-orchestrated set of events. They undergo multiple attachments to and detachments from the vessel's endothelial cells prior

to transendothelial migration. This includes slowing and rolling along the endothelial cell wall that is mediated predominantly by the interaction of selectins expressed on leukocytes (L-selectin) and on endothelial cells (P- and E-selectin) with their ligands on endothelium or immune cells, respectively. The rolling leukocytes can then be activated by chemoattractants such as chemokines released from inflammatory cells and presented on endothelium. This leads to the upregulation and increased avidity of integrins. These mediate the firm adhesion of leukocytes to endothelial cells via ligands of the immunoglobulin superfamily, e.g., intercellular adhesion molecule-1 (ICAM-1). Finally, the immune cells transmigrate through the endothelial wall mediated by immunoglobulin superfamily members (e.g., platelet-endothelial adhesion molecule-1; PECAM-1) and are directed to the sites of inflammation to initiate a host defense (reviewed by Petruzzelli, L. *et al.*, 1999; von Andrian, U. H. and Mackay, C. R., 2000).

Recent findings indicate that these events can also be involved in the endogenous control of inflammatory pain. In the model of unilateral hind paw inflammation with CFA we have shown that integrin α_4 and the chemokines CXCL2 and CXCL1 are expressed by leukocytes, while adhesion molecules such as P- and E-selectins, ICAM-1, and PECAM-1 are upregulated on endothelium in inflamed paw tissue (Mousa, S. A. *et al.*, 2000; Machelska, H. *et al.*, 2002; Brack, A. *et al.*, 2004; Machelska, H. *et al.*, 2004) (Figure 3). Expression of CXCL1 and CXCL2 mRNAs and protein contents significantly increased in inflamed tissue during the course of inflammation (Brack, A. *et al.*, 2004). Importantly, L-selectin, integrins β_2, and the CXC chemokine receptor 2 (CXCR2) are coexpressed by opioid-containing leukocytes, which have migrated to inflamed subcutaneous paw tissue (Mousa, S. A. *et al.*, 2000; Brack, A. *et al.*, 2004; Machelska, H. *et al.*, 2004). Furthermore, pretreatment of rats with a selectin blocker (fucoidin), selective antibodies against

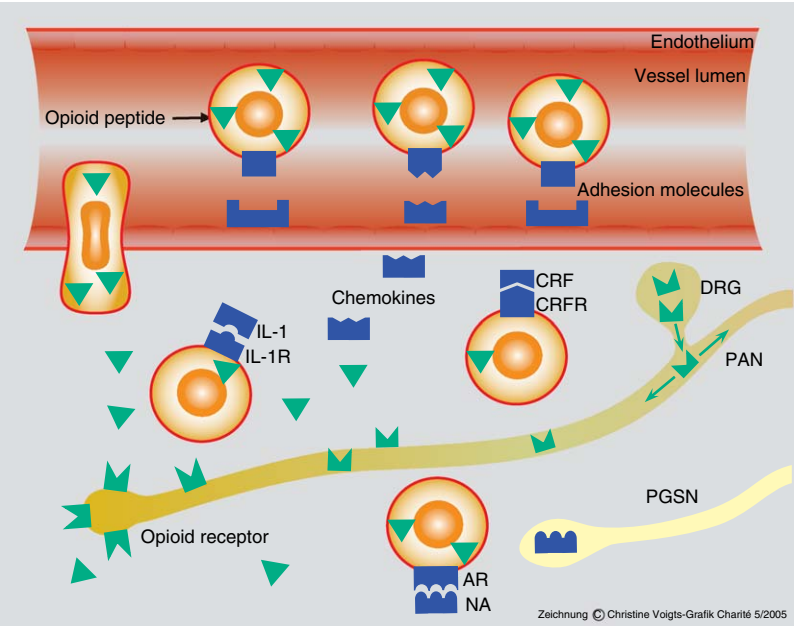

Figure 3 Migration of opioid-producing cells and opioid secretion within inflamed tissue. Adhesion molecules are upregulated on vascular endothelium and are coexpressed by circulating immune cells producing opioid peptides. These cells coexpress receptors for chemokines, which are presented on endothelium. Certain adhesion molecules mediate rolling of opioid-containing leukocytes along the endothelium. The rolling leukocytes can then be activated by chemokines, which upregulate another class of adhesion molecules mediating adhesion. Finally cells transmigrate through the endothelium. Once extravasated, these cells can be stimulated by stress or releasing agents such as corticotropin releasing factor (CRF), interleukin-1β (IL-1β), chemokines, and noradrenaline (NA) to secrete opioid peptides. CRF, IL-1, and NA (the latter derived from postganglionic sympathetic neurons; PGSN) elicit opioid release by activating CRF receptors (CRFR), IL-1 receptors (IL-1R), and adrenergic receptors (AR) on immune cells, respectively. Opioids bind to peripheral opioid receptors (produced in dorsal root ganglia (DRG) and transported to peripheral endings of primary afferent neurons; PAN) and lead to analgesia.

ICAM-1, integrins α_4 and β_2, or chemokines CXCL1 and CXCL2 substantially decreases the number of opioid-containing leukocytes infiltrating the inflamed tissue (Machelska, H. *et al.*, 1998; Machelska, H. *et al.*, 2002; Brack, A. *et al.*, 2004; Machelska, H. *et al.*, 2004) and in consequence abolishes endogenous peripheral opioid analgesia (see Endogenous Opoid Analgesia). This suggests that circulating opioid-producing immune cells home to inflamed tissue where they secrete the opioids to inhibit pain. Afterward, they travel to the regional lymph nodes, depleted of the opioid peptides (Cabot, P. J. *et al.*, 1997; 2001). Thus, local signals apparently not only stimulate the synthesis of opioid peptides in resident inflammatory cells but also attract opioid-containing cells from the circulation to the site of injury to reduce pain. This is controlled by specific chemotactic and adhesive mechanisms.

5.30.3.2.4 Release of opioid peptides from immune cells

Regulated secretion of peptides requires secretory granules deriving from the Golgi network for transport to the cell membrane. As discussed in Immune-Derived Opoid Peptides in Inflammation immune cells in the blood and in inflamed tissue coexpress the entire machinery required for POMC processing into functionally active β-endorphin (Mousa, S. A. *et al.*, 2004). Furthermore, our ultrastructural observations show that β-endorphin-expressing macrophages, monocytes, granulocytes, and lymphocytes, contain rough endoplasmic reticulum and Golgi apparatus, similar to pituitary cells. Immunostaining of β-endorphin was detectable in secretory granules, which were grouped in small or large membranous vesicular structures. The smaller β-endorphin-immunoreactive secretory granules were localized within cytoplasm, and the larger ones were arranged at the cell periphery ready for the exocytosis, similar to the pituitary (Mousa, S. A. *et al.*, 2004). In the pituitary, β-endorphin and other POMC-derived peptides are released by corticotropin releasing factor (CRF) and IL-1β (references in Schäfer, M., 2003). Similar mechanisms can trigger opioid release within peripheral inflamed tissue (Figure 3). CRF is present in immune cells, fibroblasts and vascular endothelium and peripheral CRF expression is enhanced in inflamed synovial and subcutaneous tissue of animals and humans (Schäfer, M. *et al.*, 1996). CRF and IL-1β receptors and their upregulation were demonstrated in inflamed lymph nodes and paw tissue in CFA model. Their pharmacological characteristics were similar to the high-affinity CRF- and IL-1β-binding sites in the pituitary (Mousa, S. A. *et al.*, 1996). Furthermore, the coexpression of CRF-1 and CRF-2 receptors with β-endorphin in monocytes/macrophages, granulocytes and lymphocytes were recently shown in the blood and in inflamed paw tissue (Mousa, S. A. *et al.*, 2003). In contrast, CRF receptors were not detected on peripheral sensory nerves. (Mousa, S. A. *et al.*, 1996; Mousa, S. A. *et al.*, 2003). The activation of CRF and IL-1β receptors on cells from lymph nodes results in the secretion of opioid peptides *in vitro*. In those studies β-endorphin, Met-enkephalin, and dynorphin were dose dependently released by CRF, while IL-1β released β-endorphin and dynorphin but not Met-enkephalin. These effects were specific to CRF and IL-1β receptors (Schäfer, M. *et al.*, 1994; Cabot, P. J. *et al.*, 1997; 2001; Mamet, J. *et al.*, 2002). Moreover, this release of opioid peptides was calcium-dependent and mimicked by elevated extracellular concentrations of potassium. This is consistent with a regulated pathway of release from secretory vesicles, as in neurons and endocrine cells (Cabot, P. J. *et al.*, 1997; 2001).

Adrenergic receptor agonists have also been shown to secrete β-endorphin from human peripheral blood mononuclear cells (Kavelaars, A. *et al.*, 1990). Similar mechanisms are involved in β-endorphin release from leukocytes in the rat CFA model of inflammatory pain (Binder, W. *et al.*, 2004) (Figure 3). Double labeling demonstrated adrenergic α_1-, β_2-, and, to a lesser degree, α_2 receptors expressed on β-endorphin-containing leukocytes in inflamed paw tissue. β-endorphin-containing and adrenergic α_1- and β_2-receptor-expressing immune cells were localized in close proximity to sympathetic nerve fibers, and chemical ablation of these fibers abolished intrinsic opioid analgesia. Finally, noradrenaline induced adrenergic receptor-specific release of β-endorphin from immune cells *in vitro* (Binder, W. *et al.*, 2004). Taken together, CRF, IL-1β, and sympathetic neuron-derived noradrenaline can act on their respective receptors on immune cells resulting in release of opioid peptides (Figure 3).

5.30.3.2.5 Analgesia produced by immune-derived opioid peptides

5.30.3.2.5.(i) Analgesic effects of corticotropin releasing factor, interleukin-1β, and noradrenaline

CRF-, IL-1β-, and noradrenaline-induced release of opioids from immune cells also occurs *in vivo*

(Figure 3). CRF and IL-1β injected into inflamed paws in CFA model produce dose-dependent analgesia reversible by their respective antagonists (Schäfer, M. *et al.*, 1994). CRF can produce analgesia both in early and late stages of inflammation (2 h and 6 days) and, in accord with anatomical findings (see Release of Opoid Peptides from Immune Cells), CRF analgesia involves both CRF-1 and CRF-2 receptors (Machelska, H. *et al.*, 2003; Mousa, S. A. *et al.*, 2003; Brack, A. *et al.*, 2004c). Intravenous administration of these agents in locally effective doses does not change pain thresholds, demonstrating a peripheral site of action (Schäfer, M. *et al.*, 1994; Machelska, H. *et al.*, 2003; Mousa, S. A. *et al.*, 2003; Brack, A. *et al.*, 2004c). Leukocytes apparently are the target for CRF and IL-1β because immunosuppression with cyclosporine A, depletion of granulocytes, blockade of chemokines (CXCL1 and CXCL2/3), as well as anti-selectin and anti-ICAM-1 treatments result in a significant reduction of opioid-containing immune cells and of CRF- or IL-1β-induced analgesia (Schäfer, M. *et al.*, 1994; Machelska, H. *et al.*, 1998; 2002; Brack, A. *et al.*, 2004c). Also, cyclosporine A-induced attenuation of CRF analgesia could be restored by injection of activated lymphocytes (Hermanussen, S. *et al.*, 2004). CRF- and IL-1β-induced analgesia is blocked by an antibody against β-endorphin, suggesting that this opioid plays a major role. In addition, Met-enkephalin appears to be involved in CRF-, and dynorphin in IL-1β-induced analgesia (Schäfer, M. *et al.*, 1994).

These results are in line with other studies on local analgesic effects of CRF (Hargreaves, K. M. *et al.*, 1989; McLoon, L. K. *et al.*, 2002) and of the cytokines IL-6 and TNF-α (Czlonkowski, A. *et al.*, 1993) but are in contrast to hyperalgesia mediated by IL-1β, IL-6, and TNF-α discussed in Cunha F. Q. and Ferreira S. H. (2003). Importantly, however, the latter hyperalgesic effects of exogenous cytokines were observed after injections into noninflamed tissue (Cunha, F. Q. *et al.*, 1992; Poole, S. *et al.*, 1995; Safieh-Garabedian, B. *et al.*, 1995; Woolf, C. J. *et al.*, 1997; Cunha, T. M. *et al.*, 2005). Apparently, hyperalgesia in highly inflamed tissue (4 days after CFA) has already reached a ceiling effect (Machelska, H. *et al.*, 2003) and therefore cannot be further increased. Instead, in such tissue opioid-containing immune cells became the predominant target for cytokines to produce analgesia. Contribution of endogenous proinflammatory cytokines to the generation of pain was mostly observed either in early stages (3–6 h) when cytokine blockade preceded induction of CFA inflammation (Woolf, C. J. *et al.*, 1997) or in short-lasting (30 min to 3 h) inflammation, e.g., induced with carrageenan, lipopolysaccharide, or acetic acid (Cunha, F. Q. *et al.*, 1992; Ferreira, S. H. *et al.*, 1993; Cunha, J. M. *et al.*, 2000; Cunha, T. M. *et al.*, 2005). Thus, the presence or absence of inflammation, the duration and/or model of inflammatory pain are factors to be taken into consideration.

Noradrenaline administered directly into inflamed tissue has been shown to produce analgesia, reversible by α_1-, α_2-, and β_2-adrenergic receptor antagonists in CFA model. Further, this effect was dose dependently blocked by μ and δ receptor antagonists and antibody against β-endorphin (Binder, W. *et al.*, 2004). These data suggest that this catecholamine produces analgesia via opioid peptides activating peripheral opioid receptors. In noninflamed tissue, noradrenaline did not influence pain behavior in this model, consistent with the lack of opioid-containing cells and with the scarcity of adrenergic receptors (Binder, W. *et al.*, 2004). However, the role of peripheral adrenergic receptors in nociception appears controversial. In noninflamed tissue, noradrenaline has been shown to produce hyperalgesia via α_2-adrenergic receptors. Others found that α_2-agonists could also produce peripheral analgesia. It has even been postulated that hyperalgesia is mediated via α_{2B} and analgesia is mediated via α_{2C} receptors (references in Binder, W. *et al.*, 2004). Thus, different receptor subtypes, receptor localization, microenvironment, and the presence or absence of inflammation are important parameters to be considered.

5.30.3.2.5.(ii) Endogenous opioid analgesia Stress is a natural stimulus triggering inhibition of pain (Willer, J. C. *et al.*, 1981; Terman, G. W. *et al.*, 1984). In rats, stress induced by cold water (4 °C) swim (for 1 min) elicits potent analgesia in inflamed but not in noninflamed paws in CFA model (Stein, C. *et al.*, 1990a; Machelska, H. *et al.*, 2003). In early inflammation (6 h), this swim stress-induced analgesia was only partially attenuated by peripherally selective doses of different opioid peptide antibodies and receptor antagonists but was fully reversed by centrally acting doses of an opioid receptor antagonist (Machelska, H. *et al.*, 2003). At later stages of inflammation (4–6 days), swim stress analgesia was completely abolished by peripherally selective doses of antibody against β-endorphin and by μ and δ-antagonists (Stein, C. *et al.*, 1990a). Together, these data indicate that at early stages of CFA-induced inflammation all three families of opioid

peptides and receptors are involved, while at later stages β-endorphin acting at μ- and δ-receptors dominates. Whereas at early stages both peripheral and central opioid receptors are involved, at later stages endogenous analgesia is mediated exclusively by peripheral opioid receptors. Thus, peripheral opioid mechanisms of pain control become more prevalent with the duration and severity of inflammation. Endogenous triggers of swim stress-induced analgesia are locally produced CRF and sympathetic nerve-derived catecholamines because this effect is abolished by local neutralization of CRF (Schäfer, M. *et al.*, 1996; Machelska, H. *et al.*, 2003), and by sympathetic blockade (Binder, W. *et al.*, 2004).

Various types of immune cells are the source of opioids as demonstrated by the abolishment of stress-induced analgesia by immunosuppression with cyclosporine A or whole-body irradiation and by depletion of monocytes/macrophages (Stein, C. *et al.*, 1990b; Przewlocki, R. *et al.*, 1992; Brack, A. *et al.*, 2004a). Moreover, this effect is also extinguished by inhibiting the extravasation of β-endorphin-containing immune cells following blockade of L- and P-selectins, α_4 and β_2 integrins or of ICAM-1 (Machelska, H. *et al.*, 1998; 2002; 2004). These adhesion molecules apparently regulate the migration of opioid-containing immune cells and the subsequent generation of intrinsic pain control in inflamed tissue (Figure 3).

A future challenge is to identify factors that will increase homing of opioid-containing cells to injured tissue and will enhance analgesia. To this end, we have shown that hematopoetic growth factors strongly mobilized granulocytes in the blood but resulted only in a minor increase in the number of opioid-containing leukocytes in inflamed paws and in no change of CRF- and swim stress-induced analgesia (Brack, A. *et al.*, 2004b). Another approach was to increase the migration of opioid-containing cells to inflamed tissue with local injections of CXCL2. However, this did not result in stronger CRF- or swim stress-induced analgesia either, most probably as a result of the small number of peripheral opioid receptors at this very early (2 h) stage of inflammation (Brack, A. *et al.*, 2004d). Indeed, previous studies had shown that intrinsic analgesia increases with the duration of inflammation (2 h to 4 days), in parallel with the number of opioid-containing leukocytes, with the number of peripheral opioid receptors and with the efficacy of opioid receptor–G protein coupling in sensory neurons (Mousa, S. A. *et al.*, 2001; Rittner, H. L. *et al.*, 2001; Zöllner, C. *et al.*, 2003).

5.30.3.2.6 Clinical implications

Peripheral endogenous opioid analgesia has found many clinical applications. Opioid receptors have been demonstrated on peripheral terminals of sensory nerves in human synovia (Stein, C. *et al.*, 1996) and these receptors mediate analgesia in patients with various types of pain (e.g., in chronic rheumatoid arthritis and osteoarthritis, bone pain, after dental, laparoscopic, urinary bladder, and knee surgery) (references in Stein, C. *et al.*, 2003). Opioid peptides are found in human synovial lining cells, mast cells, lymphocytes, and macrophages. The prevailing peptides are β-endorphin and Met-enkephalin, while only minor amounts of dynorphin are detectable (Stein, C. *et al.*, 1993; 1996). The interaction of synovial opioids with peripheral opioid receptors was examined in patients undergoing knee surgery. Blocking intraarticular opioid receptors by the local administration of naloxone resulted in significantly increased postoperative pain (Stein, C. *et al.*, 1993). Taken together, these findings suggest that in a stressful (e.g., postoperative) situation, opioids are tonically released from inflamed tissue and activate peripheral opioid receptors to attenuate clinical pain. Importantly, these endogenous opioids do not interfere with exogenous morphine, i.e., intraarticular morphine is an equally potent analgesic in patients with and without opioid-producing inflammatory synovial cells (Stein, C. *et al.*, 1996). This suggests that, in contrast to the rapid development of tolerance in the central nervous system, the immune cell-derived opioids do not readily produce cross-tolerance to morphine at peripheral opioid receptors.

5.30.3.2.7 Perspectives

Effective control of inflammatory pain can result from interactions between leukocyte-derived opioid peptides and their receptors on peripheral sensory neurons. These findings provide new insights into intrinsic mechanisms of pain control and open strategies to develop new drugs and alternative approaches to treatment of pain. Immunocompromised patients (e.g., in AIDS, cancer, diabetes) frequently suffer from painful neuropathies, which can be associated with intra- and perineural inflammation, with reduced intraepidermal nerve fiber density and with low $CD4^+$ lymphocyte counts (Polydefkis, M. *et al.*, 2002). Thus it may be interesting to investigate the opioid

production/release and the migration of opioid-containing leukocytes in these patients. The important role of certain adhesion molecules and chemokines in the trafficking of opioid-containing cells to injured tissues indicates that antiadhesion or antichemokine strategies for the treatment of inflammatory diseases may in fact carry a significant risk to exacerbate pain. It would be highly desirable to identify stimulating factors and strategies that selectively attract opioid-producing cells and increase peripheral opioid receptor numbers in damaged tissue. Augmenting the synthesis and/or secretion of opioid peptides and opioid receptor numbers within injured tissue may be accomplished by gene therapy: delivery of PENK, POMC, and of μ receptor cDNAs have been shown to decrease chronic pain and inflammation (Braz, J. *et al*., 2001; Lu, C. Y. *et al*., 2002; Xu, Y. *et al*., 2003).

Importantly, opioid analgesia resulting from neuroimmune interactions occurs in peripheral tissues and therefore is devoid of central opioid side effects (such as depression of breathing, nausea, clouding of consciousness, addiction, and high rate of tolerance) and of typical side effects produced by COX inhibitors (such as gastric erosions, ulcers, bleeding, diarrhea, thromboembolic events, and renal toxicity). Many efforts are currently undertaken to develop peripherally acting analgesics by aiming at individual excitatory receptors or channels on sensory neurons (Simonin, F. and Kieffer, B. L., 2002). The major advantage of targeting opioid receptors is their mechanism of action: the inhibition of calcium (and possibly sodium) channels simply renders the nociceptor less excitable to the plethora of stimulating molecules expressed in damaged tissue. Thus, peripherally acting opioids can prevent and reverse the action of multiple excitatory agents simultaneously, in contrast to blocking only one single noxious stimulus. Uncovering mechanisms that can enhance the availability of endogenous opioids within injured tissue and the signal transduction of peripheral opioid receptors will open exciting possibilities for pain research and therapy.

5.31.1 Introduction

It has been known since the early 1970s that peripheral nerve injury leads to the activation of glia in anatomically linked regions of the brain and spinal cord (Aldskogius, H. and Kozlova, E. N., 1998). In these studies, glial activation was inferred by upregulation of the so-called glial activation markers. These signs that glial activation has occurred can be visualized under the microscope using immunohistochemistry to detect cell-type specific changes (e.g., increased expression of glial fibrillary acidic protein by astrocytes; increased expression of complement type 2 receptors by microglia). Such studies revealed that damage of sensory afferent nerves activates glia in the region of the afferent terminations in the central nervous system (CNS). Likewise, damage of motor efferents activates glia in the CNS in the region of the involved motor neuron cell bodies (Aldskogius, H. and Kozlova, E. N., 1998). While this early literature documented the phenomenon of glial activation in CNS following peripheral nerve injury, the mechanisms underlying such activation remained obscure.

Two decades later, glial activation was linked to neuropathic pain. This link was again initially based on the upregulation of glial activation markers (Garrison, C. J. *et al.*, 1991; 1994). Pharmacology, anatomy, and molecular biology studies that followed documented that microglia and then astrocytes are sequentially activated in response to inflammation and damage to peripheral nerves (Raghavendra, V. *et al.*, 2003; Ledeboer, A. *et al.*, 2005). Indeed, studies of p38 mitogen-activated protein (MAP) kinase activation demonstrated that microglial activation occurs with remarkable rapidity following nerve injury (Svensson, C. I. *et al.*, 2004). Upon activation, neuroexcitatory products that glia release are importantly involved in the initiation and maintenance of neuropathic pain, via their actions on neurons of the pain pathway (Watkins, L. R. *et al.*, 2001; Watkins, L. R. and Maier, S. F., 2003). Thus, converging lines of evidence utilizing a variety of techniques all support the conclusion that glia are key players in neuropathic pain.

However, what is known to date regarding glial involvement in neuropathic pain begs a fundamentally important question: how do glia know to become activated? That is, what message(s) do glia receive that trigger their transition from basal to activated states? This will be discussed first in the context of glial activation in response to injury or inflammation of peripheral nerves, and then more broadly in the context of glial activation in response to analgesics used clinically to treat chronic pain, such as morphine and methadone.

5.31.2 Glial Activation in Response to Neurotransmitters

Given that (1) glia become activated in response to inflammation and damage of peripheral tissues and peripheral nerves and (2) this activation occurs within the somatotopically appropriate region of spinal cord, this suggests that glia may be activated by neurotransmitters released by nocisponsive primary afferents. Indeed, calcitonin gene-related peptide (CGRP) (Haas, C. A. *et al.*, 1991; Reddington, M. *et al.*, 1995), adenosine triphosphate (ATP) (Araque, A. *et al.*, 1999; Tsuda, M. *et al.*, 2003), glutamate (Araque, A. *et al.*, 1999; Tsuda, M. *et al.*, 2003), and substance P

(Svensson, C. I. *et al.*, 2003; Marriott, I., 2004) can each activate microglia and astrocytes. Such neurotransmitter-driven glial activation can be relevant for pain facilitation. For example, pain facilitation that is normally produced upon intrathecal administration of the excitatory amino acid, *N*-methyl-D-aspartate (NMDA), is abolished by blocking microglial activation (Hua, X.-Y. *et al.*, 2005).

Regarding substance P, studies of spinal cord glia have demonstrated that it can activate both astrocytes and microglia. Astrocytes isolated from spinal cord (but not from other brain regions) release prostaglandins upon exposure to substance P (Marriott, D. R. *et al.*, 1991). Substance P can also stimulate the production of proinflammatory cytokines in both astrocytes (Martin, F. C. *et al.*, 1992; Palma, C. *et al.*, 1997; Lieb, K. *et al.*, 1998) and microglia (Martin, F. C. *et al.*, 1993; Luber-Narod, J. *et al.*, 1994). When substance P is injected intrathecally in rats, this activates spinal cord microglia as reflected by phosphorylation (activation) of microglial p38 MAP kinase, a signaling pathway linked to pain facilitation (Svensson, C. I. *et al.*, 2004). Interestingly, microglia can also produce substance P, suggesting that these glial cells may potentially contribute to substance P-mediated pain signaling (Lai, J. P. *et al.*, 2002).

ATP has also recently attracted attention as a neurotransmitter that can enhance pain via the activation of glia. Microglia (but not neurons or astrocytes) express an ionotropic ATP receptor subtype called P2X4 whose expression can become dramatically upregulated in response to peripheral nerve injury (Tsuda, M. *et al.*, 2003). Pharmacological blockade of spinal P2X4 receptors and knockdown of P2X4 receptors using antisense oligodeoxynucleotides each reverse neuropathy-induced tactile allodynia (Tsuda, M. *et al.*, 2003). Intriguingly, activation of microglia by ATP is sufficient to cause pain facilitation. That is, microglia that are first stimulated *in vitro* by ATP, and then injected intrathecally in rats, induces mechanical allodynia (Tsuda, M. *et al.*, 2003).

While, at first glance, it would seem logical that glia must become activated in response to neurotransmitters released as a consequence of peripheral nerve injury, one must remember the literature of the 1970s. That is, if one damages a pure motor nerve, glia are activated surrounding the motor neuron cell bodies within the CNS. In this case, there is no damage to sensory afferent fibers. So, despite there being no neurotransmitter release, glia are still being intensely activated. Thus, while glia do express receptors for neurotransmitters and can respond to them, they are not required for glial activation to take place. This predicts that other signals, beyond neurotransmitters, must exist which can trigger the activation of glia.

5.31.3 Glial Activation in Response to Neuromodulators

Neuromodulators, such as prostaglandins and nitric oxide (NO) are well documented to enhance pain (Woolf, C. J. and Salter, M. W., 2000). In addition to direct excitatory effects on neurons, these substances can also activate glia. Using NO as the example, NO induces calcium oscillations in astrocytes, a marker of activation in this cell type. In turn, NO-induced calcium oscillations causes a nondecrementing, rapid spread of excitation to surrounding astrocytes through cell-to-cell low-resistance connections called gap junctions (Heidemann, A. C. *et al.*, 2004; Sul, J. *et al.*, 2004). Thus NO-excited astrocytes lead to the excitation of a much larger population of astrocytes. Once activated, these glia can then begin releasing neuroexcitatory substances (Araque, A. *et al.*, 1999). In addition, NO induces the release of glutamate, ATP, and prostaglandins from astrocytes (Molina-Holgado, F. *et al.*, 1995; Bal-Price, A. *et al.*, 2002) and stimulates the production of proinflammatory cytokines in both microglia and astrocytes (Sun, D. *et al.*, 1998). Regarding actions in spinal cord, NO has recently been demonstrated to drive the production and release of proinflammatory cytokines in response to intrathecally administered gp120, a protein expressed on the surface of the acquired immune deficiency syndrome (AIDS) virus that activates glia (Holguin, A. *et al.*, 2004). As gp120-induced proinflammatory cytokines induce mechanical allodynia, it would be predicted that NO synthesis inhibitors would block such pain changes concomitant with blocking NO-induced production of these cytokines. Indeed, that was the result found (Holguin, A. *et al.*, 2004).

5.31.4 Glial Activation by Unique Neuron-to-Glia Signals

Beyond neurotransmitters and neuromodulators classically known for their pain-enhancing effects, glia can also be activated by substances novel to the pain field. This class includes fractalkine and substances released by damaged cells. Regarding fractalkine, it is a protein expressed on the extracellular surface of both sensory afferent neurons and

neurons intrinsic to the spinal cord (Verge, G. M. *et al.*, 2004; Lindia, J. A. *et al.*, 2005). Fractalkine is tethered to the neurons in such a way as to be enzymatically released under strong neuroexcitatory conditions. Upon release, fractalkine acts as a diffusible signaling molecule (Chapman, G. *et al.*, 2000). Intriguingly, under basal conditions, the receptor for fractalkine is expressed predominantly by spinal microglia (Verge, G. M. *et al.*, 2004; Lindia, J. A. *et al.*, 2005). Thus, upon insult to the body, released fractalkine serves as a neuron-to-microglial signal. In response to peripheral nerve inflammation and injury, there is an increase in fractalkine receptor expression by microglia in the dorsal horn and microglia remain the sole apparent source of fractalkine receptor expression (Verge, G. M. *et al.*, 2004; Lindia, J. A. *et al.*, 2005). Under some (but not all) neuropathic conditions, astrocytes may begin producing fractalkine, suggestive that astrocytes also stimulate microglia via the release of fractalkine, so to maintain microglial activation under such conditions (Verge, G. M. *et al.*, 2004; Lindia, J. A. *et al.*, 2005).

Regarding the role of fractalkine in pain facilitation, what is known to date is that fractalkine upregulates P2X4 receptors in dorsal spinal cord microglia (Wieseler-Frank, J. *et al.*, 2004). As reviewed above, this microglia-specific ATP receptor is implicated in the induction of mechanical allodynia (Tsuda, M. *et al.*, 2003). When fractalkine is injected intrathecally, it induces both mechanical allodynia and thermal hyperalgesia, via the release of proinflammatory cytokines (Johnston, I. N. *et al.*, 2004; Milligan, E. D. *et al.*, 2004; 2005). Importantly, endogenous fractalkine enhances pain. That is, blocking fractalkine actions both delays and reverses neuropathic pain (Milligan, E. D. *et al.*, 2004). This suggests that peripheral nerve injury causes perseverative release of fractalkine and this release contributes to the induction and maintenance of neuropathic pain.

Lastly, glia can be activated by substances that signal neuronal damage. Microglia, like other immune cells, express evolutionarily conserved receptors for detecting cell damage, as well as for detecting pathogens such as bacteria and viruses. The genes for these receptors are homologous to the Toll gene in *Drosophila* and have therefore come to be referred to as Toll-like receptors (TLRs). One TLR subtype, TLR4, has been clearly implicated in pain facilitation (Tanga, F. Y. *et al.*, 2005). TLR4 knockout mice show reduced neuropathic pain in response to L5 nerve transection, as do rats treated with TLR4 antisense oligodeoxynucleotide to reduce the expression of spinal TLR4. This treatment also decreased expression of spinal microglial markers and proinflammatory cytokines, compared to controls (Tanga, F. Y. *et al.*, 2005). While TLR4 is best known as the receptor that recognizes bacterial endotoxin (lipopolysaccharide), it also binds endogenous substances associated with cell damage. These include members of the heat shock protein family and proteoglycans.

The potential link to heat shock proteins is especially intriguing. Heat shock proteins are classically thought of as intracellular proteins that aid in cell survival after stress or trauma (Costigan, M. *et al.*, 1998). However, heat shock proteins are also released by damaged and dying cells and such extracellular heat shock proteins can activate glia (Kakimura, J. *et al.*, 2002; Takata, K. *et al.*, 2003). Indeed, heat shock proteins are known to be upregulated for months in the spinal processes of sensory neurons whose peripheral axons are damaged (Costigan, M. *et al.*, 1998). Preliminary data suggest that heat shock proteins can synergize with other glial excitatory stimuli to enhance the production of proinflammatory cytokines by dorsal spinal cord microglia (Wieseler-Frank, J. *et al.*, 2004).

5.31.5 Beyond Neuropathic Pain: Glial Activation in Response to Opioids

While the focus to this point has been on endogenous signals that activate glia, it is also noteworthy that glia are activated by opioids, including morphine (Song, P. and Zhao, Z. Q., 2001; Raghavendra, V. *et al.*, 2002; Johnston, I. N. *et al.*, 2004; Shavit, Y. *et al.*, 2004) and methadone (Hutchinson, M. R. *et al.*, 2005). The results for morphine that have been reported across labs to date are remarkably consistent in demonstrating that spinal cord glia become progressively more activated by morphine upon repeated administration and that morphine-induced glial activation leads to the production and release of proinflammatory cytokines. This opioid-induced proinflammatory cytokine release has been linked, using diverse methodologies, to an attenuation of acute morphine analgesia, to the development of morphine tolerance, and to the expression of withdrawal-induced thermal hyperalgesia and mechanical allodynia (for a review, see Watkins, L. R. *et al.*, 2005). What is important about this line of research is that it documents that glia are not only activated in response to peripheral injury and inflammation, but also by first-line opioids used for clinical pain control. Thus, glial activation becomes a

double-edged sword, occurring both in response to situations that induce pathological pain and in response to drugs intended to treat it.

5.31.6 Conclusions

It is clear from the studies reviewed above that spinal cord glia can become activated in response to a wide array of chemical signals. Some are neurotransmitters and neuromodulators naturally released in spinal cord dorsal horn in response to inflammation and damage in the body, others are unique neuron-to-glia signals released by activated and damaged neurons, and surprisingly some are drugs commonly used for clinical pain control. Regardless of what the activating stimulus is, the end result is strikingly similar. That is, activated glia begin producing and releasing an array of neuroexcitatory substances, including proinflammatory cytokines. Taken together, these studies clearly predict that targeting spinal cord glia and glial proinflammatory products should suppress pain facilitation induced by inflammation and damage to peripheral tissues and enhance the clinical efficacy of opioids.

5.32.1 Introduction

At first glance the trigeminal nerve (Vn), the largest cranial nerve, serves many of the same functions as spinal nerves for lower parts of the body by relaying innocuous and noxious mechanical, thermal and chemical sensory information from all tissues of the head and oral cavity to the brain (Figure 1). Although there are many similarities, peripheral and central aspects of the Vn system are organized quite differently from the spinal system (see Table 1). A primary function of the Vn system is to detect damaging or potentially damaging environmental challenges to the head and oral cavity and one obvious distinction from spinal systems is the diversity of specialized craniofacial tissues innervated by the Vn that provide such detection. Tissues such as the dental pulp, cornea, and dura lack appreciable innervation by large diameter afferent fibers and generally evoke only pain sensation to natural stimuli (Feindel, W. *et al*., 1960; Kenshalo, D. R., 1960; Beuerman, R. W. and Tanelian, D. L., 1979; Trowbridge, H. O. *et al*., 1980). Sensory afferents that innervate mucosal tissues of the eye, nose, and oral cavity have a high sensitivity to airborne chemicals (Cometto-Muniz, J. E. and Cain, W. S., 1995) and are thought to underlie the common chemical sense in mammals (see Bryant, B. and Silver, W. L., 2000). The Vn also supplies all specialized receptor regions of the head including the fungiform taste papillas (Whitehead, M. C. *et al*., 1999), cochlea (Vass, Z. *et al*., 1997) and the eye (Belmonte, C. *et al*., 1997). In some mammals and lower vertebrates the Vn relays sensory information unrelated to nociception from unique peripheral structures over distinct central pathways to meet environmental demands. For example, Vn afferents that supply the pit organ of crotaline snakes, a highly sensitive thermal receptor with broad spectral tuning that complements visual input, do not respond to capsaicin (Moiseenkova, V. *et al*., 2003) and project to separate regions of the trigeminal brainstem complex (Molenaar, G. J., 1978). The skin of the bill of the platypus contains some 30 000–40 000 mucous sensory glands innervated by small myelinated trigeminal afferent fibers that detect electromagnetic radiation emitted by prey and used for underwater navigation (Proske, U. *et al*., 1998). The whisking of mystacial vibrissas on the face of rodents provides essential textural and perceptual information for exploration and food-gathering in a frequency-dependent manner (Petersen, C. C., 2003; Moore, C. I., 2004), whereas the trigeminal innervation of the snout of the coati mundi (Barker, D. J. and Welker,

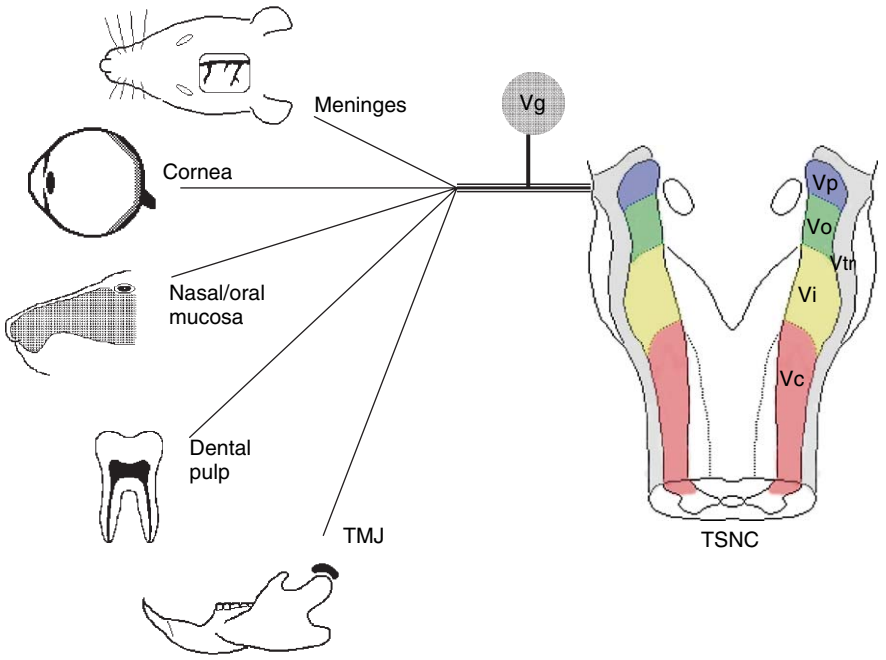

Figure 1 Unique craniofacial tissues supplied by the Trigeminal Nerve.

W. I., 1969) and Eimer's organ of the appendages of the star-nosed mole (Catania, K. C., 1999) relay highly refined tactile information and appear more analogous to somatosensory receptors of the hands than face of primates. Thus, a significant feature of the peripheral Vn is its association with highly specialized sensory functions of craniofacial and oral tissues.

The organization of the central Vn system also displays unusual features distinct from spinal systems that may be relevant to pain processing. At the level of the initial synapse, the trigeminal sensory brainstem nuclear complex (TSNC), craniofacial tissues are represented somatotopically at multiple, and in some cases discontinuous levels, while spinal nerves project to a few dominant contiguous segments (see Renehan, W. E. and Jacquin, M. F., 1993; Bereiter, D. A. *et al.*, 2000; Sessle, B. J., 2000). The importance of multiple representation remains uncertain; however, based on encoding properties and efferent projections, this feature may reflect the segregation of neuronal populations that serve different aspects of trigeminal function. Although the representation of craniofacial tissues accounts for a relatively large area of sensory thalamus and somatosensory cortex, a feature that has long been appreciated since the classic studies of Penfield W. and Rasmussen T. (1950), the cortical representation of some specialized craniofacial tissues is organized in unusual patterns (e.g., teeth) and not always proportional to innervation density (e.g., ocular surface). In lower mammals, peripheral and central specializations can lead to remarkable magnification of the cortical representation of orofacial tissues such as the nasal appendages of the star-nosed mole which accounts for over 50% of the area of primary somatosensory cortex (SmI; Catania, K. C. and Kaas, J. H., 1997). Similarly, the representation of the enlarged incisors of the naked mole rat used for tunneling and underground navigation accounts for over 30% of SmI (Catania, K. C. and Remple, M. S., 2002). In the albino rat the face occupies more than 60% of SmI with a large area devoted to the cortical barrels and mystacial vibrissae (Welker, C., 1971), whereas a significant portion of the lateral somatosensory cortex is devoted to the teeth (Remple, M. S. *et al.*, 2003). Cortical representation of craniofacial tissues in primates is much reduced compared to lower mammals; however, in select regions such as area 3b, the representation of the face and oral cavity remains unexpectedly large, though curiously, the ocular surface with its high innervation density is represented only weakly (Manger, P. R. *et al.*, 1995; Jain, N. *et al.*, 2001). Beyond the biological importance of protecting the head and oral cavity from damaging stimuli, the Vn is critical for preserving normal eating and sleeping habits, while the emotional

significance of protecting one's face and self-image suggests that the Vn system has evolved features that set it apart from spinal systems.

Chronic orofacial pain is a significant public health concern that affects more than 20% of the population in western societies (Macfarlane, T. V. *et al.*, 2002b). Persistent orofacial pain has profound effects on eating and sleeping patterns, a strong association with depression, and a reduced sense of wellbeing (Korszun, A., 2002). Many common forms of chronic orofacial pain such as headache, temporomandibular disorders (TMD), odontalgia, and dry eye are difficult to treat clinically and may be associated with lower pain thresholds elsewhere in the body (Burstein, R. *et al.*, 2000; Sarlani, E. and Greenspan, J. D., 2003; Van Bijsterveld, O. P., *et al.*, 2003). Moreover, epidemiological studies indicate that many chronic craniofacial pain conditions are more prevalent and occur with greater intensity in women than men (Lipton, J. A. *et al.*, 1993; Sandstedt, P. and Sorensen, S., 1995;

LeResche, L., 1997; Rasmussen, B. K., 2001; Wolf, E. *et al*., 2001). This review highlights several neurobiological aspects of the Vn system that differ from spinal systems and may contribute to the pattern and magnitude of craniofacial pain.

5.32.2 The Peripheral Trigeminal Nerve System

5.32.2.1 General Features

The sensory portion of the Vn consists of three main nerve branches: ophthalmic, maxillary, and mandibular. Proprioceptive afferents from select craniofacial muscles and periodontal ligaments travel within the Vn, however; the cell bodies are located in the mesencephalic nucleus of V (Vme) in the rostral pons (Cody, F. W. *et al*., 1972; Linden, R. W., 1978). Unlike the spinal dorsal root ganglion (DRG) that has no apparent intraganglionic organization, the somata of neurons giving rise to the three branches of Vn are somatotopically arranged within the trigeminal ganglion (TG; Kerr, F. W. L., 1963; Marfurt, C. F., 1981; Arvidsson, J. *et al*., 1992; Aigner, M. *et al*., 2000). Table 1 lists several features of the peripheral Vn system that differ from the spinal system. Differences relevant to pain processing include the innervation of specialized tissues, composition, and central termination of afferents; relationship of sensory nerves to sympathetic efferent outflow; and neurochemical markers in ganglion cells. The Vn innervates a heterogeneous and unique group of craniofacial tissues well associated with pain sensation. The cornea is the most densely innervated tissue of the body, supplied exclusively by small diameter fibers (Rozsa, A. J. and Beuerman, R. W., 1982); is the only tissue in which nerve fibers penetrate the outer epithelial layers (Hoyes, A. D. and Barber, P., 1976; Muller, L. J. *et al*., 1996); and responds to very small changes in ocular surface temperature, moisture status, or foreign bodies (Belmonte, C. *et al*., 1997). The oral mucosal epithelium also is densely innervated by polymodal small diameter Vn afferents with relatively large receptive fields (RFs) compared to cutaneous receptors (Toda, K. *et al*., 1997) that provide proprioceptive information on lip/tongue position necessary for eating and speech as well as detecting noxious stimuli within the mouth (Trulsson, M. and Johansson, R. S., 2002). By contrast, the dental pulp is well insulated from the exterior environment and, while pain is the predominant sensation relayed by pulpal afferents, dental afferents respond best to natural stimuli after injury (Byers, M. R., 1984; Hildebrand, C. *et al*., 1995). Specialized transduction processes also are associated with these unique tissues such as the proposed hydrodynamic movement of fluid as the basis for dentinal pain (Brannstrom, M., 1986).

Peripheral Vn afferents are subject to frequent injury due to trauma, infection, or iatrogenic damage following surgery that can lead to peripheral sensitization. Indeed, one of the first demonstrations of enhanced peripheral C-fiber activity due to injury was reported for facial afferents in the monkey (Beitel, R. E. and Dubner, R., 1976). Since peripheral sensitization of small myelinated A-δ versus unmyelinated C-fibers does not occur uniformly, but rather varies for different tissue types and depends on the nature of the injury (see Meyer, R. A. *et al*., 2006), it may be significant that the sensory root of the Vn has a greater percentage of A-δ fibers than C-fibers compared to spinal nerves as determined by counts of axons (Young, R. F. and King, R. B., 1973; Holland, G. R. and Robinson, P. P., 1992) or lectin staining for C-fibers (Ambalavanar, R. and Morris. R., 1992; Wang, H. *et al*., 1994). Correspondingly, corneal (Belmonte, C. *et al*., 1997) and dural afferents (Levy, D. and Strassman, A. M., 2002) conducting in the A-δ range display greater sensitization than more slowly conducting C-fibers.

Complex regional pain syndrome (CRSP), formerly referred to as causalgia, is a neuropathic pain condition with sympathetic involvement, often resulting from trauma or bone fracture to the distal limbs (see Wasner, G. *et al*., 1998). The incidence of CRSP-like symptoms following trauma to craniofacial tissues is relatively low compared to injury of other tissues (Matthews, B., 1989). The exact reason for this observation is not certain; however, fewer sympathetic efferent fibers course within sensory branches of Vn compared to spinal nerves, and instead these fibers travel along the arteries that supply the head and oral cavity (Hoffmann, K. D. and Matthews, M. A., 1990; Maklad, A. *et al*., 2001). Spinal nerve injury induces sprouting of noradrenergic fibers into the DRG (McLachlan, E. M. *et al*., 1993), whereas comparable injury to Vn produces no such sprouting into the TG (Bongenhielm, U. *et al*., 1999; Benoliel, R. *et al*., 2001). Furthermore, cervical sympathectomy does not alter the development of ectopic discharge or increased mechanical sensitivity after inferior alveolar nerve transection (Bongenhielm, U. *et al*., 1998). Since the basis for sprouting into the DRG following nerve injury is thought to involve neurotrophins (Davis, B. M. *et al*., 1994), it is interesting to note that the number of trkA-positive corneal and dental sensory TG

neurons is significantly less (< 10%, Mosconi, T. *et al.*, 2001) than for spinal DRG neurons (40%, Molliver, D. C. and Snider, W. D., 1997). Failure to observe sympathetic sprouting may be specific for nerve injury, since central administration of nerve growth factor (NGF) induces significant sprouting into the TG and spinal DRG (Nauta, H. J. *et al.*, 1999).

5.32.2.2 Neurochemical and Molecular Properties of Trigeminal Ganglion Neurons

Although this review emphasizes comparisons of the TG and DRG systems in the adult, significant developmental differences also exist. While the functional significance of developmental differences (e.g., neurogenic placode vs. neural crest) may not be obvious in the healthy adult, many responses to injury recapitulate developmental differences and thus may have implications in the injured adult nervous system. Studies reporting similarities in development of the TG and DRG systems have included: P2X3 receptor expression (Ruan, H. Z. *et al.*, 2004); phenotype expression in trkB knockout mice (Klein, R. *et al.*, 1993; Gonzalez-Martinez, T. *et al.*, 2004); vesicular monoamine transporter levels (Hansson, S. R. *et al.*, 1998); the apoptotic enzyme, CPP32/apopain (Mukasa, T. *et al.*, 1997); neuronal tyrosine hydroxylase (Son *et al.*, 1996; Kim, S. J. *et al.*, 1997); six 4/ARECC3 mRNA (Esteve, P. and Bovolenta, P., 1999); the transcription factor, retinoid-X receptor γ (Georgiades, P. *et al.*, 1998); guanosine triphosphate (GTP)-binding protein G-α z (Kelleher, K. L. *et al.*, 1998); the fetal plasma glycoprotein, fetuin (Kitchener, P. D. *et al.*, 1997); FGF receptor mRNA (Wanaka, A. *et al.*, 1991); and the large zinc finger protein, KRC (Hicar, M. D. *et al.*, 2002). By contrast, studies reporting significant differences in the developing TG and DRG systems have included: expression of trkC at day 12.5 (DRG: yes, TG: no; Elkabes, S. *et al.*, 1994); requirement for NGF at day E16.5 (DRG > TG; Goedert, M. *et al.*, 1984); and sensitivity to cadmium-induced neurotoxicity (TG > DRG; Arvidson, B., 1983). Thus, developmental biology indicates some similarities with notable differences in the responsiveness to certain neurotrophic factors.

Table 2 summarizes results from studies comparing adult TG and DRG systems under basal (naive) conditions. These studies reveal many similarities among markers associated with nociception such as the percentage of TRPV1-positive neurons (Ambalavanar, R. *et al.*, 2005) and expression of P2X receptor subtypes (Collo, G. *et al.*, 1996; Cook, S. P. *et al.*, 1997; Xiang, Z. *et al.*, 1998). However, substantial differences also are observed that include: the percentage of neurons stained for substance P and somatostatin (TG > DRG; Kai-Kai, M. A., 1989), trkA receptor (DRG > TG; Mosconi, T. *et al.*, 2001), galectin-1 (DRG >> TG; Akazawa, C. *et al.*, 2004), μ- and δ-opioid receptors (DRG > TG; Buzas, B. and Cox, B. M., 1997), CCK (DRG > TG; Ghilardi, J. R. *et al.*, 1992), cytokeratin (TG >> DRG; Okabe, H. *et al.*, 1997), and neuropeptide Y (NPY)-binding sites (TG > DRG; Mantyh, P. W. *et al.*, 1994). In addition, TG and DRG systems display a differential sensitivity to ganglion cell labeling by selected anatomical tracers in which the TG system has a greater uptake of Fluoro-Gold than DRG but not of Fast Blue (Yoshimura, N. *et al.*, 1994).

Differences in cellular properties between the TG and DRG systems under naive conditions may contribute to differential responses to tissue injury. For example, sprouting of sympathetic nerve terminals into the DRG (McLachlan, E. M. *et al.*, 1993), but not the TG after nerve injury (Bongenhielm, U. *et al.*, 1999; Benoliel, R. *et al.*, 2001) is consistent with findings that trkA-positive neurons are more numerous in the DRG than TG (Mosconi, T. *et al.*, 2001). Comparison of nerve injury-induced changes for a majority of neuropeptides associated nociception such as substance P, TRPV1, P2X3, and NPY appear similar for TG and DRG systems (Zhang, X. *et al.*, 1996; Okuse, K. *et al.*, 1997; Eriksson, J. *et al.*, 1998; Elcock, C. *et al.*, 2001; Tsuzuki, K. *et al.*, 2001; Stenholm, E. *et al.*, 2002; Tsuzuki, K. *et al.*, 2003). However, species differences have been reported such as a decrease in galanin in TG of ferret (Elcock, C. *et al.*, 2001) compared to an increase in rat (Zhang, X. *et al.*, 1996) after Vn injury, similar to the increase in galanin in rat DRG after spinal nerve injury (Villar, M. J. *et al.*, 1989). Nerve injury causes higher spontaneous discharge rates and greater rhythmic firing patterns in DRGs than TGs (Tal, M. and Devor, M., 1992), effects often associated with sodium channel activity (see Wood, J. N. *et al.*, 2004). However, the basis for this difference is not certain since changes in the expression of the tetrodotoxin (TTX)-resistant sodium channel, NaV1.8, appear comparable for DRG and TG systems (Dib-Hajj, S., *et al.*, 1996; Bongenhielm, U. *et al.*, 2000). Susceptibility to infection also may differ between TG and DRG systems, since injection of herpes simplex virus (HSV) to the left ear pinna in

mice produces 100% HSV infection in both the ipsilateral TG and cervical DRG. Interestingly, 70% of the TGs contralateral to injection, while only 10% of contralateral DRGs were infected (Thackray, A. M. and Field, H. J., 1996). Interhemispheric neural communication likely contributes to the progression of joint-related pain in trigeminal (see Bereiter, D. A. *et al.*, 2005b) as well as spinal systems (Levine, J. D. *et al.*, 1985; Shenker, N. *et al.*, 2003). The responsiveness to viral vectors in the Vn system has prompted recent efforts to deliver targeted transgene-derived products for control of trigeminal neuropathic pain (Meunier, A. *et al.*, 2005). Collectively, these studies reveal significant differences in peripheral Vn and spinal systems under naïve and injured conditions, differences that could not be predicted on the basis of results from spinal sensory systems alone.

5.32.3 Central Aspects of Trigeminal Organization

Noxious sensory information is relayed from Vn afferents to second-order neurons in the TSNC and the upper cervical spinal cord. The TSNC is the initial site of synaptic integration for sensory input from the head and oral cavity and shares this feature with the spinal dorsal horn and dorsal column nuclei that receive sensory input from the rest of the body (Figure 1). However, unlike the spinal cord, the TSNC is comprised of several cell groups with distinct cytological and organizational features (see Darian-Smith, I., 1973; Kruger, L. and Young, R. F., 1981) yet each cell group receives direct primary afferent projections from specific craniofacial tissues. The TSNC consists of: the principal nucleus (Vp), supratrigeminal region (Vsup) lying dorsal to Vp, an elongated spinal nucleus (Vsp) extending from the pons to the upper cervical spinal cord, and the interstitial islands or the paratrigeminal region (Pa5) embedded within the spinal trigeminal tract, dorsal and lateral to the caudal Vsp (Figure 2; see Kruger, L. and Young, R. F., 1981; Renehan, W. E. and Jacquin, M. F., 1993). The Vsp is further subdivided, from rostral to caudal, into subnucleus oralis (Vo), subnucleus interpolaris (Vi), and a laminated trigeminal subnucleus caudalis (Vc) as described originally by Olszewski J. (1950). Although nociceptive neurons in the caudal laminated portion of the TSNC, Vc, display properties similar to those at spinal levels (Price, D. D. *et al.*, 1976; Dubner, R. and Bennett, G. J., 1983) consistent with a prominent role in nociceptive processing (see also Bereiter, D. A. *et al.*, 2000; Sessle, B. J., 2000), the contribution of rostral portions of the TSNC to orofacial pain is less certain.

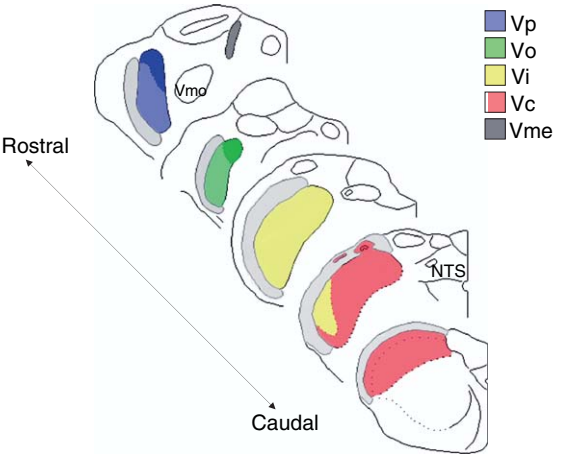

Figure 2 Trigeminal brainstem sensory complex.

5.32.3.1 Somatotopy

Somatotopy is a key feature of the trigeminal system and is seen within the TG as well as the TSNC distinct from the spinal cord. Craniofacial tissues are represented at multiple levels of the TSNC, while sensory afferents from other body loci terminate at several contiguous spinal segments of the spinal dorsal horn. Also, at caudal levels of the TSNC craniofacial tissues are represented in a series of semicircular bands that converge at the rostral midline of the face, often referred to as an onion-skin arrangement and by a medial-lateral representation in which the head is inverted (Jacquin, M. F. *et al.*, 1986; Shigenaga, Y. *et al.*, 1986a). Although somatotopy along the mediolateral axis is preserved at all levels of the TSNC, the onion-skin arrangement is most apparent in Vc. The implications of this organization for facial pain have been debated since an early report by Sjoqvist O. (1938) that trigeminal tractotomy at the level of rostral Vc reduced the pain of trigeminal neuralgia, while preserving the sense of temperature and touch on the face. It is understood that rostral portions of TSNC play a more prominent role in dental and intraoral pain than caudal portions (Young, R. F. and Perryman, K. M., 1984; see Sessle, B. J., 2000); however, the importance of multiple representation of extraoral tissues for other forms of craniofacial pain is not well understood. One reason for this uncertainty may be due to the fact that many craniofacial tissues are represented in a discontinuous manner along the rostrocaudal extent of the TSNC as summarized in Table 3. Although a small percentage of Vn afferents projects to both rostral and caudal portions of the TSNC (Silverman, J. D. and Kruger, L., 1985; Li, Y. Q. *et al.*, 1992), most fibers either ascend in a short sensory root to terminate in Vp or descend to give off branches to Vo, Vi, Vc, and the upper cervical dorsal horn. Several aspects of the afferent input pattern to TSNC are notable. First, the superficial laminas in Vc receive substantial input from all specialized tissues well associated with craniofacial pain conditions (e.g., cornea, dura, teeth, temporomandibular joint (TMJ)), while afferents from structures with no known relationship to pain perception (vibrissas) do not project to this region. Second, dental pulp afferents are the

only group of putative nociceptive fibers with a substantial projection to rostral portions of the TSNC, namely, to the dorsomedial portions of Vp and Vo, thus supporting the role for these regions in intraoral pain (Marfurt, C. F. and Turner, D. F., 1984; Shigenaga, Y. *et al.*, 1986c). Also, compared to other orofacial tissues associated with pain sensation, the termination pattern of dental afferents is particularly widespread along the rostrocaudal extent of the TSNC. Third, input from structures supplied by the ophthalmic branch of the Vn (e.g., cornea, nasal dura) project only sparsely to rostral portions of the TSNC suggesting that these regions play a lesser role than Vc in mediating pain due to uveitis, dry eye, sinusitis, or headache. Fourth, discontinuous representation is not unique to tissues supplied by the ophthalmic division (e.g., cornea, dura, nasal cavity) since the auriculotemporal nerve, a major source of innervation for the TMJ region also displays an uneven terminal distribution in the TSNC (Shigenaga, Y. *et al.*, 1986a; 1986b). In rodents vibrissae afferents project to most levels of the TSNC (Arvidsson, J., 1982; Nomura, S. *et al.*, 1986); however, the architectonic representation of the vibrissae fields, the so-called barrelettes, are well delineated in Vp, Vi, and Vc, but not Vo (Ma, P. M., 1991), supporting the notion that different levels of the TSNC mediate different aspects of sensory processing of innocuous as well as noxious inputs.

5.32.3.2 Intersubnuclear Connections

Rostral and caudal portions of the TSNC are connected by a rich longitudinal fiber network coursing within spinal trigeminal tract and through the deep bundles that extend from Vp to the upper cervical spinal cord (Gobel, S. and Purvis, M. B., 1972; Kruger, L. *et al.*, 1977; Ikeda, M. *et al.*, 1984; Jacquin, M. F. *et al.*, 1990). Although propriospinal-like connections of the TSNC share anatomical similarities with those at lower spinal levels, intersubnuclear connections in the TSNC link spatially distinct brainstem regions with common somatotopic representation of facial fields. The implications of this organization for facial pain remain to be determined; however, results from numerous animal studies support the clinical findings of Sjoqvist O. (1938) and indicate that ascending connections from caudal Vc generally facilitate the activity of neurons in more rostral portions within the TSNC. Lesion or chemical blockade of caudal Vc reduced the excitability of rostral trigeminal neurons responsive to noxious stimulation of tooth pulp (Greenwood, L. F. and Sessle, B. J., 1976; Chiang, C. Y. *et al.*, 2002), dura (Davis, K. D. and Dostrovsky, J. O., 1988), and cornea (Hirata, H. *et al.*, 2003). By contrast, innocuous sensory input from facial skin (Greenwood, L. F. and Sessle, B. J., 1976) and vibrissae (Hallas, B. H. and Jacquin, M. F., 1990) often was enhanced. Fewer studies have assessed the influence of rostral TSNC regions on caudal Vc neural activity, though in a recent study, muscimol blockade of the Vi/Vc transition region facilitated cornea-responsive neurons in laminas I–II of caudal Vc (Hirata, H. *et al.*, 2003). These results suggest that ascending as well as descending connections within the TSNC contribute to the integration of sensory inputs relevant for craniofacial pain.

5.32.3.3 Relationship to the Autonomic Nervous System

The trigeminal system is closely linked to brain regions that control autonomic outflow, especially parasympathetic outflow and vagus nerve activity. This linkage likely contributes to craniofacial pain conditions such as primary headache (Edvinsson, L. and Uddman, R., 2005) and dry eye (Hocevar, A. *et al.*, 2003), sudden bradycardia and asystole during maxillofacial surgery (Schaller, B., 2004), and the so-called diving reflex in infant humans (Goksor, E. *et al.*, 2002) and aquatic mammals (Butler, P. J. and Jones, D. R., 1997). Even facial skin differs from other cutaneous regions in that it is well supplied by parasympathetic fibers (Ramien, M. *et al.*, 2004). Under experimental conditions noxious stimulation of craniofacial tissues in humans evokes long-lasting vasodilatation in orofacial regions (Drummond, P. D., 1992; Izumi, H., 1999) that differs from responses evoked by stimulation of other body regions consistent with the existence of specialized trigeminal vasodilator reflex mechanisms (Kemppainen, P. *et al.*, 2001). Two aspects of the relationship between autonomic nerves and the trigeminal system are distinct from spinal cord and deserve special mention. Unlike at spinal levels where nearly all sensory nerves relay initially in the dorsal horn or dorsal column nuclei, many Vn afferents, especially those from the mandibular branch, project directly to brainstem nuclei that control autonomic outflow such as the nucleus tractus solitarius (NTS), parabrachial complex, and ventrolateral medulla (Kerr, F. W. L., 1961; Jacquin, M. F. *et al.*, 1983; Marfurt, C. F. and Rajchert, D. M., 1991; Panneton, W. M., 1991; Panneton, W. M. *et al.*, 1994). Also, unlike lower portions of the spinal cord, there is an extensive convergence of Vn, facial, glossopharyngeal, and vagal afferents to common laminae of

the lower TSNC and upper cervical dorsal horn (Denny-Brown, D. and Yanagisawa, N., 1973; Beckstead, R. M. and Norgren, R., 1979; Contreras, R. J. *et al.*, 1982; Altschuler, S. M. *et al.*, 1989; McNeill, D. L. *et al.*, 1991). The dorsal paratrigeminal region (dPa5) also receives inputs from multiple cranial nerves and upper cervical rootlets, has widespread connections to central autonomic pathways and other regions of the TSNC, and may be a key site of somatic–autonomic integration for cutaneous and visceral sensory input and control of homeostasis (Panneton, W. M. and Burton, H., 1985; Saxon, D. W. and Hopkins, D. A., 1998; Caous, C. A. *et al.*, 2001). Considerable evidence suggests that the Vc/upper cervical cord (Vc/C2) junction region differs from lower spinal cord. In addition to receiving convergent input from multiple cranial nerves and upper cervical rootlets (Pfaller, K. and Arvidsson, J., 1988; Neuhuber, W. L. and Zenker, W., 1989), second-order Vc/C2 neurons have widespread ascending connections to the hypothalamus (Burstein, R. *et al.*, 1990) and periaqueductal gray (PAG; Keay, K. A. *et al.*, 1997), brainstem regions well associated with control of autonomic outflow, and endogenous pain modulation circuits. The Vc/C2 junction also sends long-range descending projections to the lower spinal cord and is a critical region for visceral sensory, particularly vagus nerve, modulation of somatic input to lower spinal segments (Chandler, M. J. *et al.*, 2002). Although vagus nerve stimulation generally is associated with antinociception in humans (Kirchner, A. *et al.*, 2000) and animals (Randich, A. and Gebhart, G. F., 1992; Khasar, S. G. *et al.*, 1998), the relationship between vagus nerve activity and facial pain may be more complex. For example, increased vagal afferent activity has been suggested as one source of facial pain referred from the lung in cancer patients (see Sarlani, E. *et al.*, 2003), whereas in animal studies increased vagal activity inhibits painlike behavior and c-fos expression after formalin injection into facial skin (Bohotin, C. *et al.*, 2003) and tooth pulp-evoked activity of Vc/C2 dorsal horn neurons (Tanimoto, T. *et al.*, 2002). The effects of vagus nerve stimulation have been tested mainly on neurons in the caudal portions of the TSNC; however, vagal stimulation also inhibits tooth pulp-evoked digastric reflexes (Bossut, D. F. *et al.*, 1992) suggesting that modulation of neurons in rostral portions of the TSNC is possible. Given the extensive convergence and efferent projections of second-order neurons at the dPa5 and Vc/C2 regions, it is tempting to speculate that trigeminal–vagal interactions play a significant role in modulating pain above as well as below the neck.

5.32.3.4 Neurochemical Markers

The role of central neurons in mediating the various aspects of pain (e.g., sensation, autonomic control, motor reflexes) can be predicted, in part, on the basis of key factors such as the nature of the sensory input, encoding properties, response to analgesic agents, efferent projections (Price, D. D. and Dubner, R., 1977; Price, D. D. *et al.*, 2003), and, more recently, the distribution of a growing list of neurochemical markers associated with nociceptive processing (Woolf, C. J. and Salter, M. W., 2000; Julius, D. and Basbaum, A. I., 2001; Lewin, G. R. *et al.*, 2004). The data provided in Tables 4 (neurochemical markers) and 5 (efferent projections) are consistent with the notion that different portions of the TSNC contribute to different aspects of craniofacial pain. However, these data derive from results in naïve animals and do not specifically indicate which regions respond with phenotypic or long-term structural changes during chronic pain (see Basbaum, A. I., 1999; Hunt, S. P. and Mantyh, P. W., 2001; Scholz, J. and Woolf, C. J., 2002), changes that likely occur unequally in different portions of the TSNC.

Table 4 summarizes the pattern of distribution of selected neurochemical markers with known association to nociceptive processing and/or its modulation. The most striking aspect of these data is the dense and almost universal distribution of all markers within the superficial laminae of Vc, while only weak labeling is seen in laminae not associated with nociceptive processing (laminae III–IV). In rostral portions of the TSNC the density of different markers is more varied than in Vc. For example, the dorsomedial portions of Vp and Vo, regions that have a high density of afferent terminals from tooth pulp nerves, also display intense labeling for calcitonin gene-related peptide (CGRP) and trkA, whereas labeling for substance P and inositol 1,4,5 triphosphate (IP3) receptor are relatively weak and that for MOR1, the μ-opioid receptor, is absent. Interestingly, selective agonists for the 5-HT_{1B} receptor, a serotonergic receptor subtype that binds sumatriptan, an effective therapeutic agent for migraine, displays moderate density in the dorsomedial portions of Vp and Vo, yet neither region receives significant input from meningeal afferents. Although the laminar distribution of most neurochemical markers in Vc and the spinal dorsal horn are similar, significant differences have been reported for IB4 (Sugimoto, T. *et al.*, 1997a) and TRPV1 (Bae, Y. C. *et al.*, 2004), where spinal lamina IIi contains a greater expression of both markers than lamina IIo, while the reverse is seen in Vc. Also, the distribution of CGRP and substance P appears

more widely distributed across laminae I–III in Vc than in spinal dorsal horn where both neuropeptides are restricted to laminae I and IIo. The functional significance of these differences are not certain; however, the high degree of convergence of afferents from multiple sensory ganglion sources (e.g., trigeminal, nodose, cervical dorsal root) to the caudal Vc may underlie the poor localization and spreading of pain for many craniofacial pain conditions.

TSNC independent of the functional class (i.e., nociceptive versus innocuous sensory encoding). These data derive largely from studies in rodents; however, the qualitative pattern of efferent projections from the TSNC is similar across species, although there are significant quantitative species differences for some targets. Efferent projections from second-order neurons to the sensory thalamus have commanded considerable attention. The main sources of projections from the TSNC to the ventral posterior medial nucleus (VPM) arise from Vp and Vi, which in the case of rodents and most carnivores, is due to a heavy projection from vibrissae-driven rather than nociceptive neurons (Veinante, P. *et al.*, 2000). Nociceptive neurons in Vc that project to VPM originate mainly in laminae I and V (Ikeda, M. *et al.*, 2003) and moreover, the majority of projection neurons are found in rostral Vc rather than near the Vc/C2 junction region (Guy, N. *et al.*, 2005). Lamina I of Vc projects heavily to the posterior thalamus (PO); however, ventrolateral portions of Vo also provide a significant input to PO (Guy, N. *et al.*, 2005). Both Vc and spinal dorsal horn lamina I cells project to similar though adjacent regions of PO (Gauriau, C. and Bernard, J. F., 2004). Projections to parafascicular thalamic nuclei from Vc are sparse compared to spinal dorsal horn (Craig, A. D., 2004; Gauriau, C. and Bernard, J. F., 2004). Trigeminal projections to thalamic nucleus submedius (SM) reveal a unique pattern that differs markedly from spinal cord and exhibits significant species differences. In the rat the majority of SM projections arise from the ventrolateral portion of the Vi/Vc transition region with only weak input from lamina I and V of caudal Vc, while spinal projections to SM originate mainly from laminae V–VII (Dado, R. J. and Giesler, G. J., 1990; Yoshida, A. *et al.*, 1991). By contrast, in cat and monkey lamina I cells in Vc and spinal cord provide a significant direct input to SM with Vc displaying a somewhat more extensive projection (Craig A. D. and Burton, H., 1981). Trigeminal projections to autonomic control regions such as hypothalamus, parabrachial area, and NTS derive mainly from the dPa5, the Vi/Vc transition and lamina I of Vc, while more rostral regions of the TSNC provide relatively sparse input. This pattern is consistent with the dPa5 and lamina I of Vc receiving direct input from the vagus nerve. Spinal lamina I cells also project heavily to similar autonomic control regions of the brainstem (Cechetto, D. F. *et al.*, 1985; Menetrey, D. and Basbaum, A. I., 1987; Westlund, K. N. and Craig, A. D., 1996). Although nociceptive neurons in Vc (Sessle, B. J. *et al.*, 1981; Chiang, C. Y. *et al.*, 1994) and Vo (Chiang, C. Y. *et al.*, 1989) are markedly inhibited by direct stimulation of PAG or rostral ventromedial medulla (RVM), the afferent pathways from second-order TSNC neurons to these endogenous pain control regions are not well defined. Compared to the significant input from upper cervical levels of spinal cord (Keay, K. A. *et al.*, 1997) projections from TSNC to PAG are sparse (Beitz, A. J., 1982). These results add substantial support to the notion that laminae I–II of Vc are critical regions for processing nociceptive information relevant for multiple aspects of craniofacial pain. Behavioral evidence, though less extensively tested compared to spinal pain models, indicates that the Vc is necessary for opioid modulation of cutaneous facial pain (Oliveras, J. L. *et al.*, 1986) and that levels of attention markedly influence Vc nociceptive neurons and behavioral responsiveness (Hayes, R. L. *et al.*, 1981).

5.32.4 Functional Considerations

Recent developments in methods that assess neural activity and encoding properties provide the strongest evidence regarding the functional role of different regions of the TSNC in craniofacial pain. Advances in neuroimaging can distinguish somatotopic and simultaneous activation of brainstem and cortical responses to trigeminal stimuli in conscious humans (DaSilva, A. F. *et al.*, 2002), though resolution is not yet sufficient to discern the relative activation of different portions of the TSNC. Nociceptive neurons in the TSNC have been identified and their properties determined mainly on the basis of electrophysiological recording and, more recently, immediate early gene expression such as c-*fos*. Immunostaining for Fos, the protein product of c-*fos*, is a reliable method to identify populations of nociceptive central neurons at the single cell level (see Bullitt, E., 1990), an advantage not readily achieved by electrophysiology. Although there are examples of mismatches, properly designed c-*fos* studies generally complement electrophysiological results and have shed new light on long-standing controversies in trigeminal physiology. For example, a role for Vo in dental pain is suggested by: a dense terminal pattern in dorsomedial Vo from tooth pulp afferents (Marfurt, C. F. and Turner, D. F., 1984), a moderate-to-high density of CGRP staining (Sugimoto, T. *et al.*, 1997b), and behavioral studies revealing preservation of dental pain after trigeminal

tractotomy at the level of caudal Vi (Young, R. F. and Perryman, K. M., 1984). By contrast, few Vo neurons can be driven by natural stimulation of the tooth pulp compared to Vc (Hu, J. W. and Sessle, B. J., 1984) and few Fos-positive neurons are found in Vo after acute thermal stimulation of teeth (Chattipakorn, S. C. *et al.*, 1999). Thus, despite the fact that many Vo cells can be classified as nociceptive on the basis of cutaneous RF properties (Dallel, R. *et al.*, 1990), display wind-up to repeated cutaneous stimulation (Dallel, R. *et al.*, 1999), and are inhibited by systemic morphine (Dallel, R. *et al.*, 1996), the role of Vo in acute dental pain remains uncertain. It is possible that the Vo acts as a silent pain relay in the TSNC and becomes active only after persistent tissue damage since Fos-positive cells first appear in Vo only several days after molar tooth pulp exposure (Byers, M. R. *et al.*, 2000) and Vo neurons display sensitization provided input from Vc remains intact (Chiang, C. Y. *et al.*, 2002; Hu, B. *et al.*, 2002). Alternatively, rostral TSNC contributions to intraoral sensation and homeostasis may involve nonpulpal tissues (e.g., periodontal, muscosal receptors) and mediate select aspects of craniofacial pain (e.g., somatomotor reflexes).

5.32.4.1 Ocular Pain Processing

Ascribing a role for different portions of the TSNC in ocular pain appears more straightforward than for dental pain.

Corneal afferents terminate mainly in ventrolateral portions of caudal Vi and Vc with few fibers projecting to more rostral regions (Panneton, W. M. and Burton, H., 1981; Marfurt, C. F. and del Toro, D. R., 1987; Marfurt, C. F. and Echtenkamp, S. F., 1988). Acute stimulation of the ocular surface in the rat evokes a high density of Fos-positive cells at the Vi/Vc transition and caudal Vc and none in rostral regions of TSNC (Lu, J. *et al.*, 1993; Strassman, A. M. and Vos, B. P., 1993; Bereiter, D. A. *et al.*, 1994; Meng, I. D. and Bereiter, D. A., 1996). Converging lines of evidence support the notion that the Vi/Vc transition and caudal Vc serve different aspects of ocular pain.

All ocular cells in laminae I–II at the Vc/C2 junction are classified as nociceptive (wide-dynamic range (WDR), nociceptive specific (NS)), while many cells at the Vi/Vc transition have no cutaneous RF (Meng, I. D. *et al.*, 1997; Hirata, H. *et al.*, 1999). Many cells at the Vi/Vc transition are sensitive to the moisture status of the ocular surface, while few such neurons are found in caudal Vc, suggesting that this region is critical for reflex lacrimation (Hirata, H. *et al.*, 2004).

Repeated ocular surface stimulation evokes a wind-up like response among caudal Vc units, while Vi/Vc cells rapidly become desensitized (Meng, I. D. *et al.*, 1997). In a model for endotoxin-induced uveitis, at 7days after ocular inflammation convergent cutaneous RF areas become enlarged and responsiveness to ocular surface stimulation is enhanced among caudal Vc neurons, while Vi/Vc transition cells display no evidence of hyperalgesia (Bereiter, D. A. *et al.*, 2005c).

Systemic morphine inhibits all ocular cells at the caudal Vc, while nearly 30% of Vi/Vc cells are enhanced; an effect that can be produced by microinjection of μ-opioid receptor agonists directly into the caudal Vc (Meng, I. D. *et al.*, 1998; Hirata, H. *et al.*, 2000).

The modality of ocular units at the Vi/Vc and caudal Vc predicts, in part, the efferent projections to PO or salivatory nucleus in the brainstem (Hirata, H. *et al.*, 2000). The Vi/Vc transition is unique among TSNC regions and is the main source of ascending projections to SM (Yoshida, A. *et al.*, 1991; Ikeda, M. *et al.*, 2003). These data suggest that the caudal Vc underlies the sensory-discriminative aspects of ocular pain and modulation of ocular cells in more rostral regions via intersubnuclear connections. By contrast, the Vi/Vc transition appears to play a significant role in mediating ocular-specific reflexes (e.g., lacrimation, eye blink). Projections to SM, coupled with the finding that many Vi/Vc neurons display enhanced responsiveness after morphine, suggests that this region may be part of the neural circuit that recruits endogenous pain controls in response to craniofacial tissue injury. Since a high percentage of ocular cells at each region also respond to meningeal stimulation (Strassman, A. M. *et al.*, 1994; Burstein, R. *et al.*, 1998; Schepelmann, K. *et al.*, 1999), it is proposed that rostral and caudal portions of Vc mediate different aspects of headache as well as ocular pain.

5.32.5 Chronic Craniofacial Pain

Chronic pain involving craniofacial tissues is a significant public health concern and a recognized research priority for the National Institutes of Health (NIH; e.g., PA 03-173: *Neurobiology of Persistent Pain Mediated by the Trigeminal Nerve*). The classification, diagnosis, and management of

chronic craniofacial pain remain difficult since the mechanisms for many of these conditions are not well understood and animal models, though instructive, do not mimic the clinical state (Vos, B. P. *et al.*, 1994; Roveroni, R. C. *et al.*, 2001). Considerable progress has been in delineating the long-term changes in peripheral and central neural circuits that mediate pain sensation following tissue injury (Treede, R. D. *et al.*, 1992; Woolf, C. J. and Salter, M. W., 2000; Hunt, S. P. and Mantyh, P. W., 2001; Julius, D. and Basbaum, A. I., 2001; Lewin, G. R. *et al.*, 2004). Although similar cellular and molecular mechanisms may contribute to chronic pain due to Vn damage (Lavigne, G. *et al.*, 2005), many chronic craniofacial pain conditions such as TMD, migraine, or chronic daily headache and trigeminal neuralgia present with no overt signs of tissue injury. Indeed, it has long been appreciated that the correlation between tissue injury and magnitude of pain sensation may be weak (Wall, P. D., 1979). This has lead to proposals of emotional or neuropsychological (Tenenbaum, H. C. *et al.*, 2001; Korszun, A., 2002) and genetic factors as significant determinants of some forms of chronic craniofacial pain (TMD, Diatchenko, L. *et al.*, 2005; migraine, Wessman, M. *et al.*, 2004; trigeminal neuralgia, Duff, J. M., *et al.*, 1999; dry eye in Sjogren's syndrome, Takei, M. *et al.*, 2005). Chronic craniofacial pain can be broadly classified according to the pattern and origin of pain episodes: chronic/recurrent (TMD, migraine headache, trigeminal neuralgia), chronic/persistent (burning mouth, dry eye syndromes), and chronic deafferentation pain (postherpetic neuralgia, posttraumatic neuralgia, phantom tooth). The mechanisms that underlie these diverse conditions involve markedly different tissues and are likely quite heterogeneous. However, three features of many chronic craniofacial pain conditions are notable and provide evidence of commonality.

First, the prevalence of most chronic craniofacial pain conditions is higher in women than men (Dao, T. T. and LeResche, L., 2000; Macfarlane, T. V. *et al.*, 2002a). This is especially apparent for the chronic/recurrent conditions of TMD and migraine headache (LeResche, L., 1997; Rasmussen, B. K., 200l) and somewhat less so for trigeminal neuralgia (Kitt, C. A. *et al.*, 2000; Manzoni, G. C. and Torelli, P., 2005). Women also are more likely to develop burning mouth (Bergdahl, M. and Bergdahl, J., 1999; Grushka, M. *et al.*, 2003) and dry eye syndromes (Yazdani, C. *et al.*, 2001) and report greater sensory disturbances after Vn damage (Sandstedt, P. and Sorensen, S., 1995). Among TMD (Isselee, H. *et al.*, 2002; LeResche, L. *et al.*, 2003) and migraine patients (Rasmussen, B. K., 1993; MacGregor, E. A. and Hackshaw, A., 2004) pain severity and symptoms vary over the menstrual cycle suggesting a significant interaction with factors related to sex hormone status. Correspondingly, recent anatomical (Amandusson, A. *et al.*, 1996; Pajot, J. *et al.*, 2003; Bereiter, D. A. *et al.*, 2005a; 2005b; Puri, V. *et al.*, 2005) and electrophysiological evidence (Okamoto, K. *et al.*, 2003; Flake, N. M. *et al.*, 2005) from animal models support the notion that estrogen preferentially enhances the excitability of trigeminal neurons that contribute to craniofacial pain. Furthermore, within the TSNC, estrogen receptor-positive neurons are found almost exclusively within the superficial laminae of Vc and not in more rostral portions of the complex (Bereiter, D. A. *et al.*, 2005a) suggesting that this region plays a key role in differential processing of orofacial sensory information under different sex hormone conditions.

Second, spreading and referral of pain and sensitization evoked from outside the affected dermatomal region are common features of many chronic craniofacial pain conditions. Sensory disturbances occurring outside the affected region have been well documented in clinical studies of TMD (Maixner, W. *et al.*, 1998; Sarlani, E. and Greenspan, J. D., 2003; 2005), migraine (Burstein, R. *et al.*, 2000; Katsarava, Z., *et al.*, 2002; Goadsby, P. J., 2005), trigeminal neuralgia (Dubner, R. *et al.*, 1987; Nurmikko, T. J. and Eldridge, P. R., 2001; Devor, M. *et al.*, 2002), and burning mouth syndrome (Svensson, P. *et al.*, 1993; Ito, M. *et al.*, 2002). Patients with postherpetic neuralgia involving trigeminal dermatomes had lower thermal warm and cool thresholds, while those with infection of spinal dermatomes had elevated thresholds (Pappagallo, M. *et al.*, 2000) suggesting different underlying pathologies for neuropathic pain in trigeminal and spinal systems. Mechanical allodynia and increased temporal summation are consistent with the notion that central neural mechanisms maintain chronic craniofacial pain, while peripheral mechanisms are required mainly for initiation of the pain state.

Third, many chronic craniofacial pain conditions are accompanied by significant disturbances of the autonomic and/or endocrine systems. Chronic TMD patients display altered secretion of stress hormones (Jones, D. A. *et al.*, 1997; Korszun, A. *et al.*, 2002) and elevated levels of neuropeptides and proinflammatory cytokines that could affect blood flow to joints (Kopp, S., 2001). The relationship between vascular reactivity and migraine has long been considered a

critical variable (Janig, W., 2003; Goadsby, P. J., 2005), whereas stimulus-evoked oral mucosal blood flow is greater in patients with burning mouth syndrome (Heckmann, S. M. *et al.*, 2001). Evidence from animal models indicate that contributions from vagus nerve activity (Khasar, S. G. *et al.*, 2001) and adrenal medullary outflow (Green, P. G. *et al.*, 2001) have marked sex-related effects on cutaneous pain behavior. Although treatments to reduce sympathetically maintained pain generally have a poor outcome for posttraumatic trigeminal neuralgic patients (Gregg, J. M., 1990), the influence of the autonomic nervous system on other forms chronic craniofacial pain has not been adequately explored. It may be significant that brainstem regions critically involved in control of autonomic outflow also are densely stained for estrogen receptor-positive neurons (Shughrue, P. J. *et al.*, 1997; Simonian, S. X. *et al.*, 1998; Merchenthaler, I. *et al.*, 2004). Collectively, these features underscore the hypothesis that an interaction between sex hormone status and autonomic outflow occurs within the central nervous system to alter the expression of chronic craniofacial facial pain.

We recognize that chronic craniofacial pain is a complex problem with varying etiologies and possible contributions from genetic, neuropsychological, and neurobiological factors. However, regardless of the origin and relative contribution of these factors on pain circuits within the brain, a greater understanding of the unique organizational features of the trigeminal system may provide new perspectives and strategies to manage chronic craniofacial pain that would not otherwise be apparent from studies conducted only at the spinal level.

5.33.1 Introduction

Headache in general, and in particular migraine (Goadsby, P. J. *et al.*, 2002) and cluster headache (Goadsby, P. J., 2002), is better understood now than has been the case for the last four millennia (Lance, J. W. and Goadsby, P. J., 2005). Migraine is a common, disabling recurrent disorder of the central nervous system with a core manifestation involving activation, or the perception of activation, of trigeminal nociceptive afferents (Olesen, J. *et al.*, 2005). Here how studies of the anatomy and physiology of the pain-producing innervation of the dura mater and large cranial vessels, the trigeminovascular system, has contributed to our current understanding of one of the most common maladies of humans will be explored.

5.33.2 Migraine – Explaining the Clinical Features

Migraine is in essence a familial episodic disorder whose key marker is headache with certain associated features (Table 1). It is these features that give clues to its pathophysiology, and ultimately will provide insights leading to new treatments.

The essential elements to be considered are:

Genetics of migraine;

Physiological basis for the aura;

Anatomy of head pain, particularly that of the trigeminovascular system;

Physiology and pharmacology of activation of the peripheral branches of ophthalmic branch of the trigeminal nerve;

Table 1 International Headache Society features of migraine (Headache Classification Committee of the International Headache Society, 2004)

Repeated episodic headache (4–72 h) with the following features:	
Any two of:	Any one of:
unilateral	nausea/vomiting
throbbing	photophobia and phonophobia
worsened by movement	
moderate or severe	

Physiology and pharmacology of the trigeminal nucleus, in particular its caudal most part, the trigeminocervical complex (TCC);

Brainstem and diencephalic modulatory systems that influence trigeminal pain transmission and other sensory modality processing.

5.33.3 Genetics of Migraine

One of the most important aspects of the pathophysiology of migraine is the inherited nature of the disorder. It is clear from clinical practice that many patients have first-degree relatives who also suffer from migraine (Lance, J. W. and Goadsby, P. J., 2005). Transmission of migraine from parents to children has been reported as early as the seventeenth century, and numerous published studies have reported a positive family history.

5.33.3.1 Genetic Epidemiology

Studies of twin pairs are the classical method to investigate the relative importance of genetic and environmental factors. A Danish study included 1013 monozygotic and 1667 dizygotic twin pairs of the same gender, obtained from a population-based twin register. The pairwise concordance rate was significantly higher among monozygotic than dizygotic twin pairs ($P < 0.05$). Several studies have attempted to analyze the possible mode of inheritance in migraine families and conflicting results have been obtained. Both twin studies and population-based epidemiological surveys strongly suggest that migraine without aura is a multifactorial disorder, caused by a combination of genetic and environmental factors.

5.33.3.2 Familial Hemiplegic Migraine

In approximately 50% of the reported families, familial hemiplegic migraine (FHM) has been assigned to chromosome 19p13. Few clinical differences have been found between chromosome 19-linked and unlinked FHM families. Indeed, the clinical phenotype does not associate particularly with the known mutations. The most striking exception is cerebellar ataxia, which occurs in approximately 50% of the chromosome 19-linked, but in none of the unlinked families. Another less striking difference includes the fact that patients from chromosome 19-linked families are more likely to have attacks that can be triggered by minor head trauma or are that associated by coma.

The biological basis for the linkage to chromosome 19 is mutations (Ophoff, R. A. *et al.*, 1996) involving the $Ca_v2.1$ (P/Q) type voltage-gated calcium channel *CACNA1A* gene. Now known as FHM-I, this mutation is responsible for about 50% of identified families. Mutations in the *ATP1A2* gene have been identified to be responsible for about 20% of FHM families. Interestingly, the phenotype of some FHM-II involves epilepsy, while it has also been suggested that alternating hemiplegia of childhood can be due to *ATP1A2* mutations. The latter cases are most unusual for migraine. Most recently mutations in the neuronal voltage-gated sodium channel *SCN1A* have been identified as the cause of FHM-III, thus continuing the ionopathic theme.

Taken together, the known mutations suggest that migraine, or at least the neurological manifestations currently called the aura, are caused by an ionopathy. Linking the channel disturbance for the first time to the aura process has demonstrated that human mutations expressed in a knockin mouse produce a reduced threshold for cortical spreading depression (CSD), which has some profound implications for understanding that process.

5.33.4 Migraine Aura

Migraine aura is defined as a focal neurological disturbance manifest as visual, sensory, or motor symptoms (Headache Classification Committee of the International Headache Society, 2004). It is seen in about 30% of patients, and it is clearly neurally driven. The case for the aura being the human equivalent of the CSD of Leao has been

well made (Lauritzen, M., 1994). In humans, visual aura has been described as affecting the visual field, suggesting the visual cortex, and it starts at the center of the visual field and propagates to the periphery at a speed of 3 mm min^{-1}. This is very similar to spreading depression described in rabbits. Blood flow studies in patients have also shown that a focal hyperemia tends to precede the spreading oligemia, and again this is similar to what would be expected with spreading depression. After this passage of oligemia, the cerebrovascular response to hypercapnia in patients is blunted while autoregulation remains intact. Again this pattern is repeated with experimental spreading depression. Human observations have rendered the arguments reasonably sound that human aura has as its equivalent in animals in CSD. An area of controversy surrounds whether aura triggers the rest of the attack, and is indeed painful. Based on the available experimental and clinical data this author is not at all convinced that aura is painful *per se*, but this does not diminish its interest or the importance of understanding it. Indeed therapeutic developments may shed further light on these relationships, and studies are required to understand how in some patients aura is clearly not a sufficient trigger to pain.

5.33.5 Headache – Anatomy

5.33.5.1 The Trigeminal Innervation of Pain-Producing Intracranial Structures

Surrounding the large cerebral vessels, pial vessels, large venous sinuses, and dura mater is a plexus of largely unmyelinated fibers that arise from the ophthalmic division of the trigeminal ganglion and in the posterior fossa from the upper cervical dorsal roots. Trigeminal fibers innervating cerebral vessels arise from neurons in the trigeminal ganglion that contain substance P and calcitonin gene-related peptide (CGRP), both of which can be released when the trigeminal ganglion is stimulated either in humans or cats (Goadsby, P. J. *et al.*, 1988). Stimulation of the cranial vessels, such as the superior sagittal sinus (SSS), is certainly painful in humans (Wolff, H. G., 1948). Human dural nerves that innervate the cranial vessels largely consist of small diameter myelinated and unmyelinated fibers that almost certainly subserve a nociceptive function.

5.33.6 Headache Physiology – Peripheral Connections

5.33.6.1 Plasma Protein Extravasation

Moskowitz M. A. (1990) has provided a series of experiments to suggest that the pain of migraine may be a form of sterile neurogenic inflammation. Although this seems clinically implausible, the model system has been helpful in understanding some aspects of trigeminovascular physiology. Neurogenic plasma extravasation can be seen during electrical stimulation of the trigeminal ganglion in the rat. Plasma extravasation can be blocked by ergot alkaloids, indomethacin, acetylsalicylic acid, and the serotonin-5-$HT_{1B/1D}$ agonist, sumatriptan. The pharmacology of abortive antimigraine drugs has been reviewed in detail. In addition there are structural changes in the dura mater that are observed after trigeminal ganglion stimulation. These include mast cell degranulation and changes in postcapillary venules including platelet aggregation. While it is generally accepted that such changes, and particularly the initiation of a sterile inflammatory response, would cause pain, it is not clear whether this is sufficient of itself, or requires other stimulators, or promoters. Preclinical studies suggest that CSD may be a sufficient stimulus to activate trigeminal neurons, although this has been a controversial area.

Although plasma extravasation in the retina, which is blocked by sumatriptan, can be seen after trigeminal ganglion stimulation in experimental animals, no changes are seen with retinal angiography during acute attacks of migraine or cluster headache. A limitation of this study was the probable sampling of both retina and choroids elements in rats, given that choroidal vessels have fenestrated capillaries. Clearly, however, blockade of neurogenic plasma protein extravasation is not completely predictive of antimigraine efficacy in humans as evidenced by the failure in clinical trials of substance P, neurokinin-1 antagonists, specific plasma protein extravasation (PPE) blockers, CP122,288 and 4991w93, an endothelin antagonist, and a neurosteroid. The implications of these data have been recently reviewed (Peroutka, S. J., 2005).

5.33.6.2 Sensitization and Migraine

While it is highly doubtful that there is a significant sterile inflammatory response in the dura mater during migraine, it is clear that some form of sensitization takes

place during migraine, since allodynia is common. About two-thirds of patients complain of pain from non-noxious stimuli, allodynia (Selby, G. and Lance, J. W., 1960). A particularly interesting aspect is the demonstration of allodynia in the upper limbs ipsilateral and contralateral to the pain. This finding is consistent with at least third-order neuronal sensitization, such as sensitization of thalamic neurons, and firmly places the pathophysiology within the central nervous system. Sensitization in migraine may be peripheral with local release of inflammatory markers, which would certainly activate trigeminal nociceptors. More likely in migraine is a form of central sensitization, which may be classical central sensitization, or a form of disinhibitory sensitization with dysfunction of descending modulatory pathways (Knight, Y. E. *et al.*, 2002). Just as dihydroergotamine (DHE) can block trigeminovascular nociceptive transmission, probably at least by a local effect in the TCC, DHE can block central sensitization associated with dural stimulation by an inflammatory soup, as can cyclo-oxygenase block both sensitization and trigeminocervical transmission.

5.33.6.3 Neuropeptide Studies

Electrical stimulation of the trigeminal ganglion in both humans and cats leads to increases in extracerebral blood flow and local release of both CGRP and SP (Goadsby, P. J. *et al.*, 1988). In the cat trigeminal ganglion stimulation also increases cerebral blood flow by a pathway traversing the greater superficial petrosal branch of the facial nerve (Goadsby, P. J. and Duckworth, J. W., 1987) again releasing a powerful vasodilator peptide, vasoactive intestinal polypeptide (VIP; May, A. and Goadsby, P. J., 1999). Interestingly, the VIPergic innervation of the cerebral vessels is predominantly anterior rather than posterior, and this may contribute to this region's vulnerability to spreading depression, explaining why the aura is so very often seen to commence posteriorly. Stimulation of the more specifically vascular pain-producing superior sagittal sinus increases cerebral blood flow and jugular vein CGRP levels. Human evidence that CGRP is elevated in the headache phase of migraine (Goadsby, P. J. *et al.*, 1990), supporting the view that the trigeminovascular system may be activated in a protective role in these conditions. Moreover, nitric oxide (NO)-donor-triggered migraine, which is in essence typical migraine, also results in increases in CGRP that are blocked by sumatriptan, just as in spontaneous migraine (Goadsby, P. J. and Edvinsson, L., 1993). It is of interest in this regard that compounds that have not shown activity in migraine (Peroutka, S. J., 2005), notably the conformationally restricted analogue of sumatriptan, CP122,288, and the conformationally restricted analog of zolmitriptan, 4991w93, were both ineffective inhibitors of CGRP release after superior sagittal sinus in cats. The recent development of nonpeptide highly specific CGRP antagonists, and the announcement of proof-of-concept for a CGRP antagonist in acute migraine (Olesen, J. *et al.*, 2004), firmly establishes this as a novel and important new emerging principle for acute migraine. At the same time the lack of any effect of CGRP blockers on plasma protein extravasation, explains in some part why that model has proved inadequate at translation into human therapeutic approaches (Peroutka, S. J., 2005).

5.33.7 Headache Physiology – Central Connections

5.33.7.1 The Trigeminocervical Complex

Fos immunohistochemistry is a method for looking at activated cells by plotting the expression of Fos protein. After meningeal irritation with blood Fos expression is noted in the trigeminal nucleus caudalis, while after stimulation of the superior sagittal sinus Fos-like immunoreactivity is seen in the trigeminal nucleus caudalis and in the dorsal horn at the C_1 and C_2 levels in cats and monkey. These latter findings are in accord with similar data using 2-deoxyglucose measurements with superior sagittal sinus stimulation. Similarly, stimulation of a branch of C_2, the greater occipital nerve, increases metabolic activity in the same regions, i.e., trigeminal nucleus caudalis and $C_{1/2}$ dorsal horn, and fos expression can be elicited by injection of mustard oil into the occipital muscles. In experimental animals one can record directly from trigeminal neurons with both supratentorial trigeminal input and input from the greater occipital nerve, a branch of the C_2 dorsal root (Bartsch, T. and Goadsby, P. J., 2002). Stimulation of the greater occipital nerve for 5 min results in substantial increases in responses to supratentorial dural stimulation, which can last for over 1 h. Conversely, stimulation of the middle meningeal artery dura mater with the C-fiber irritant mustard oil sensitizes responses to occipital muscle stimulation. Taken together these data suggest convergence of cervical and ophthalmic inputs at the level of the second-order neuron. Moreover, stimulation of a lateralized

structure, the middle meningeal artery, produces Fos expression bilaterally in both cat and monkey brains. This group of neurons from the superficial laminas of trigeminal nucleus caudalis and $C_{1/2}$ dorsal horns should be regarded functionally as the TCC.

These data demonstrate that trigeminovascular nociceptive information comes by way of the most caudal cells. This concept provides an anatomical explanation for the referral of pain to the back of the head in migraine. Moreover, experimental pharmacological evidence suggests that some abortive antimigraine drugs, such as, ergot derivatives, acetylsalicylic acid, sumatriptan, eletriptan, naratriptan, rizatriptan, and zolmitriptan can have actions at these second-order neurons that reduce cell activity and suggest a further possible site for therapeutic intervention in migraine. This action can be dissected out to involve each of the 5-HT_{1B}, 5-HT_{1D}, and 5-HT_{1F} receptor subtypes, and are consistent with the localization of these receptors on peptidergic nociceptors. Interestingly, triptans also influence the CGRP promoter, and regulate CGRP secretion from neurons in culture, as well as perhaps require cell surface expression for their effect. Furthermore, the demonstration that some part of this action is postsynaptic with either 5-HT_{1B} or 5-HT_{1D} receptors located nonpresynatically offers a prospect of highly anatomically localized treatment options (Figure 1).

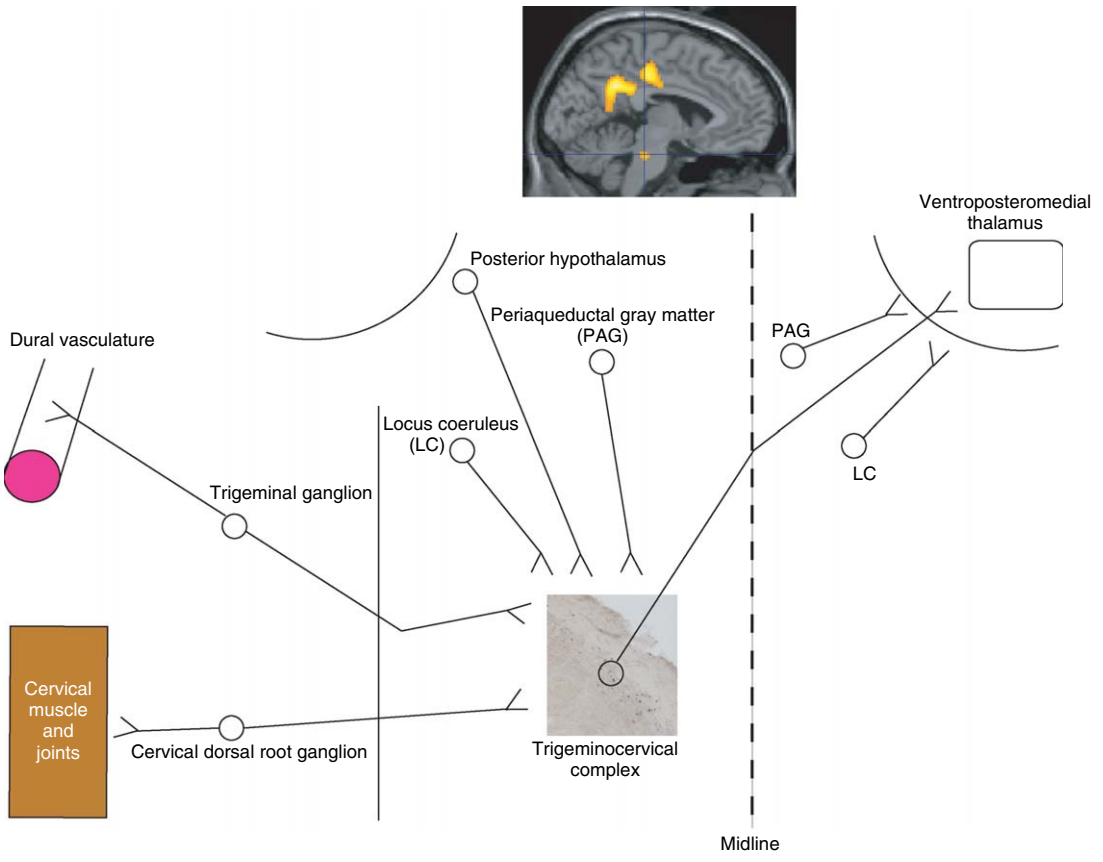

Figure 1 Illustration of the some elements of migraine biology. Patients inherit a dysfunction in brain control systems for pain and other afferent stimuli, which can be triggered and are in turn capable of activating the trigeminovascular system as the initiating event in a positive feedback of neurally driven vasodilatation. Nociceptive afferents from the cervical region terminate in the trigeminocervical complex (illustrated by Fos protein expression in the superficial laminas) and this accounts for the nontrigeminal distribution of pain in many patients. These afferents project to the thalamus, including ventroposteromedial thalamus, and are at least influenced by neurons in the posterior hypothalamic gray, the periaqueductal gray (PAG), and probably by neurons of the nucleus locus coeruleus in the pons. Functional brain imaging suggests that the brainstem, notably the pons as illustrated after Bahra, A., Matharu, M. S., Buchel, C., Frackowiak, R. S. J., and Goadsby, P. J. 2001. Brainstem activation specific to migraine headache. Lancet 357, 1016–1017, is a pivotal region in the migraine process.

Table 2 Neuroanatomical processing of vascular head pain

	Structure	*Comments*
Target innervation: Cranial vessels Dura mater	Ophthalmic branch of trigeminal nerve	
First	Trigeminal ganglion	Middle cranial fossa
Second	Trigeminal nucleus (quintothalamic tract)	Trigeminal nucleus caudalis and C_1/C_2 dorsal horns
Third	Thalamus	Ventrobasal complex Medial nucleus of posterior group Intralaminar complex
Modulatory	Midbrain Hypothalamus	Periaqueductal gray matter ?
Final	Cortex	Insulas Frontal cortex Anterior cingulate cortex Basal ganglia

5.33.7.2 Higher-Order Processing

Following transmission in the caudal brainstem and high cervical spinal cord information is relayed rostrally (Table 2).

5.33.7.2.1 Thalamus

Processing of vascular nociceptive signals in the thalamus occurs in the ventroposteromedial (VPM) thalamus, medial nucleus of the posterior complex, and in the intralaminar thalamus. It has been shown by application of capsaicin to the superior sagittal sinus that trigeminal projections with a high degree of nociceptive input are processed in neurons particularly in the ventroposteromedial thalamus and in its ventral periphery. These neurons in the VPM can be modulated by activation of gamma-aminobutyric acid $(GABA)_A$ inhibitory receptors, and perhaps of more direct clinical relevance by propranolol though a β_1-adrenoceptor mechanism (Shields, K. G. and Goadsby, P. J., 2005). Remarkably, triptans through $5\text{-}HT_{1B/1D}$ mechanisms can also inhibit VPM neurons locally, as demonstrated by microiontophoretic application, suggesting a hitherto unconsidered locus of action for triptans in acute migraine. Human imaging studies have confirmed activation of thalamus contralateral to pain in acute migraine (Bahra, A. *et al.*, 2001).

5.33.7.2.2 Activation of modulatory regions

Stimulation of nociceptive afferents by stimulation of the superior sagittal sinus in cats activates neurons in the ventrolateral periaqueductal gray matter (PAG). PAG activation in turn feeds back to the TCC with an inhibitory influence. PAG is clearly included in the area of activation seen in positron emission tomography (PET) studies in migraineurs. This typical negative feedback system will be further considered below as a possible mechanism for the symptomatic manifestations of migraine.

Another potentially modulatory region activated by stimulation of nociceptive trigeminovascular input is the posterior hypothalamic gray. This area is crucially involved in several primary headaches, notably cluster headache (Goadsby, P. J., 2002), Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT), paroxysmal hemicrania and hemicrania continua. Moreover, the clinical features of the premonitory phase, and other features of the disorder, suggest dopamine neuron involvement. Orexinergic neurons in the posterior hypothalamus can be both pro- and antinociceptive, offering a further possible region whose dysfunction might involve the perception of head pain.

5.33.8 Central Modulation of Trigeminal Pain

5.33.8.1 Brain Imaging in Humans

Functional brain imaging with PET has demonstrated activation of the dorsal midbrain, including the PAG, and in the dorsal pons, near the locus coeruleus, in studies during migraine without aura.

Dorsolateral pontine activation is seen with PET in spontaneous episodic and chronic migraine, and with nitrogylcerin-triggered attacks (Bahra, A. *et al.*, 2001; Afridi, S. *et al.*, 2005). These areas are active immediately after successful treatment of the headache but are not active interictally. The activation corresponds with the brain region that Raskin initially reported, and confirmed, to cause migrainelike headache when stimulated in patients with electrodes implanted for pain control. Similarly, excess iron in the PAG of patients with episodic and chronic migraine, and chronic migraine can develop after a bleed into a cavernoma in the region of the PAG, or with a lesion of the pons. What could dysfunction of these brain areas lead to?

5.33.8.2 Animal Experimental Studies of Sensory Modulation

It has been shown in experimental animals that stimulation of nucleus locus coeruleus, the main central noradrenergic nucleus, reduces cerebral blood flow in a frequency-dependent manner (Goadsby, P. J. *et al.*, 1982) through an α_2-adrenoceptor-linked mechanism. This reduction is maximal in the occipital cortex. While a 25% overall reduction in cerebral blood flow is seen, extracerebral vasodilatation occurs in parallel (Goadsby, P. J. *et al.*, 1982). In addition, the main serotonin-containing nucleus in the brainstem, the midbrain dorsal raphe nucleus, can increase cerebral blood flow when activated. Furthermore, stimulation of PAG will inhibit sagittal sinus-evoked trigeminal neuronal activity in cats, while blockade of P/Q-type voltage-gated Ca^{2+} channels in the PAG facilitates trigeminovascular nociceptive processing (Knight, Y. E. *et al.*, 2002) with the local GABAergic system in the PAG still intact.

5.33.8.3 Electrophysiology of Migraine in Humans

Studies of evoked potentials and event-related potentials provide some link between animal studies and human functional imaging. Authors have shown changes in neurophysiological measures of brain activation but there is much discussion as to how to interpret such changes (Schoenen, J. *et al.*, 2003). Perhaps the most reliable theme is that the migrainous brain does not habituate to signals in a normal way. Similarly, contingent negative variation (CNV), an event related potential, is abnormal in migraineurs compared to controls. Changes in CNV predict attacks and preventive therapies alter, normalize, such changes. Attempts to correlate clinical phenotypes with electrophysiological changes, may enhance further studies in this area.

5.33.9 What is Migraine?

Migraine is an inherited, episodic disorder involving sensory sensitivity. Patients complain of pain in the head that is throbbing, but there is no reliable relationship between vessel diameter and the pain, or its treatment. They complain of discomfort from normal lights and the unpleasantness of routine sounds. Some mention otherwise pleasant odors are unpleasant. The anatomical connections of, for example, the pain pathways are clear, the ophthalmic division of the trigeminal nerve subserves sensation within the cranium and explains why the top of the head is headache, and the maxillary division is facial pain. The convergence of cervical and trigeminal afferents explains why neck stiffness or pain is so common in primary headache. The genetics of channelopathies is opening up a plausible way to think about the episodic nature of migraine. However, where is the lesion, what is actually the pathology?

Migraine aura cannot be the trigger alone, there is no evidence at all after 4000 years that it occurs in more than 30% of migraine patients; aura can be experienced without pain at all, and is seen in the other primary headaches. Perhaps electrophysiological changes in the brain have been mislabeled as hyperexcitability whereas dyshabituation might be a simpler explanation. If migraine was basically an attentional problem with changes in cortical synchronization (Niebur, E. *et al.*, 2002), hypersynchronization, all its manifestations could be accounted for in a single over-arching pathophysiological hypothesis of a disturbance of subcortical sensory modulation systems. While it seems likely that the trigeminovascular system, and its cranial autonomic reflex connections, the trigeminal-autonomic reflex (May, A. and Goadsby, P. J., 1999), act as a feed-forward system to facilitate the acute attack, the fundamental problem in migraine is in the brain. Unraveling its basis will deliver great benefits to patients and considerable understanding of some very fundamental neurobiological processes.

Glossary

ASIC receptors Acid-sensing ion channels that detect low pH, a typical condition of pulpitis.

atypical odontalgia A condition in which tooth pain derives from neuropathic or referred mechanisms. Tooth extractions or root canals do not relieve the pain.

BK receptors Activated by the inflammatory mediator, bradykinin.

convergence Many sensory afferents from multiple tissues project to individual central trigeminal neurons.

dentin Specialized, calcified, collagenous matrix that surrounds the pulp.

hot tooth An inflamed tooth that resists regional anesthesia and remains sensitive when neighboring teeth are numb.

hypersensitive dentin Sharp pain elicited from light touch to exposed dentin.

ionotropic receptors Activated by specific ligands causing ion flux through receptor pores.

mesencephalic trigeminal nucleus Location of cell bodies of primary sensory neurons that innervate stretch receptors in periodontal ligament, sutures, or mastication muscles.

metabotropic receptors Interaction with ligand activates G-protein intracellular signaling.

NK receptors Receptors for neurokinins such as substance P or neurokinin A.

nucleus caudalis Caudal region of spinal trigeminal subnuclei, specialized for processing, relaying and modulating orofacial pain.

odontalgia Tooth pain.

odontoblast Neural crest-derived cells that make dentin and regulate the pulp–dentin barrier.

P2 receptors Purinergic nucleotide receptors that respond to adenosine triphosphate (ATP).

periapex Region at base of root socket that surrounds the root apex, and includes periodontal ligament, neurovascular bundles and endings, and alveolar bone.

prepain The first sensation (tingling, vibration, or touch) elicited by electrical stimulation of teeth. It changes to sharp tooth pain at stronger levels of stimulation.

pulpitis Inflamed tooth pulp that can be healed locally (reversible), that can consume the pulp and spread into periapex (irreversible), or that can be undetected (silent) until it reaches the periapex.

receptive field Patch of tissue that activates a primary afferent or central neuron.

referred pain Pain that is felt at a different site from the neural activity that causes it.

Ruffini mechanoreceptors Complex stretch mechanoreceptors located in periodontal ligament.

Trk receptors Tyrosine kinase receptors that respond to neurotrophin factors.

TRP receptors Transient receptor potential channels (vanilloid receptor family) that are activated by capsaicin, heat, or low pH.

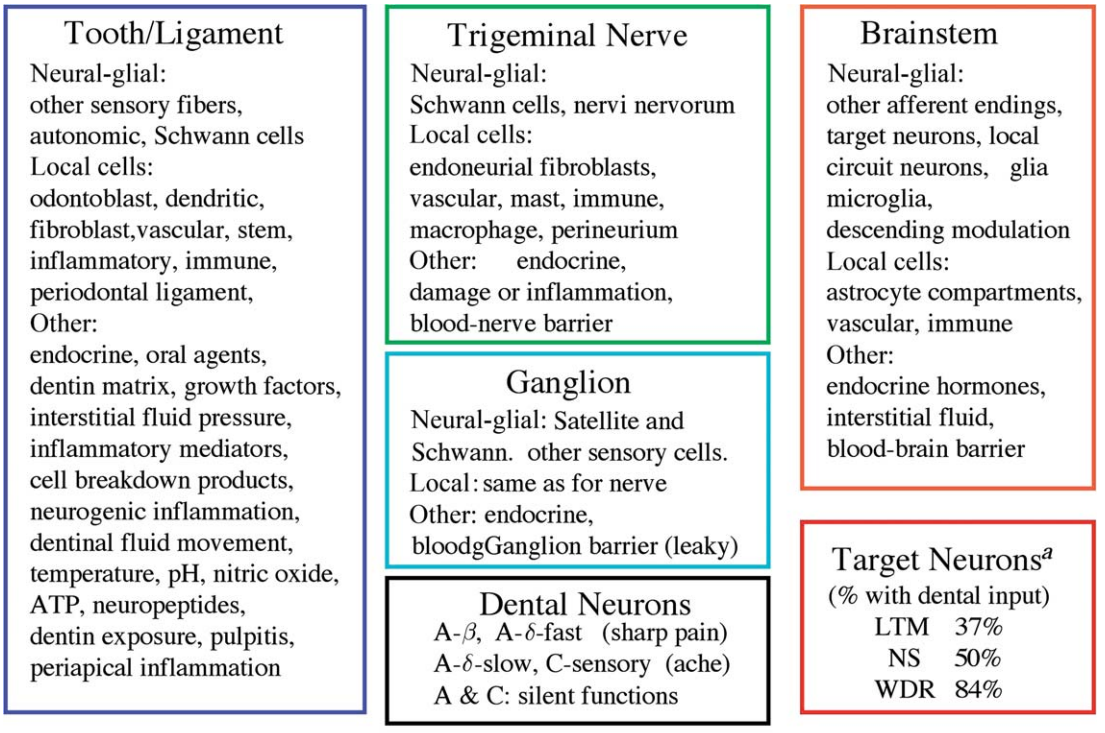
5.34.1 Introduction

Tooth pain is the most common type of orofacial pain (Lipton, J. *et al.*, 1993; Hargreaves, K. M., 2002). Dental nerve fibers branch centrally to activate many neurons in the trigeminal brainstem complex or extratrigeminal relay sites, and those central neurons also receive extensive convergent input from other orofacial tissues, making location of tooth pain difficult. However, most of the time our teeth do not hurt, and most dental neural activity is unperceived. The sensory functions of tooth nerves are presented here, along with unusual features of central processing, mechanisms, perception, diagnosis, and treatment of tooth pain, which can be sharp or dull, focused or diffuse, episodic or relentless, referred or neuropathic (for reviews see: Närhi, M. V. O. *et al.*, 1996; Olgart, L., 1996; Byers, M. R. and Närhi, M. V. O., 1999; Dionne, R. A. and Berthold, C. W., 2001; Byers, M. R. and Närhi, M. V. O., 2002; Hargreaves, K. M., 2002; Hu, J. W., 2004; Lavigne, G. *et al.*, 2004; Truelove, E., 2004; Sessle, B. J., 2005; Henry, M. A. and Hargreaves, K. M., 2007).

5.34.2 Dental Sensory Mechanisms

5.34.2.1 Normal Teeth/Acute Pain

A-fibers respond especially well to acute stimuli that move fluid in dentin (Brännström, M and Åström, A., 1972) and C-fibers respond to acute heat stimuli or pulp damage (Närhi, M. V. O. *et al.*, 1996; Närhi, M. V. O., 2005). Different factors affect axonal conduction in trigeminal nerves, ganglion, central tracts, and synaptic termination regions in the brainstem (Figure 1). Dental afferents project to low threshold mechanoreceptive, nociceptive-specific, and wide-dynamic-range central neurons, all of which receive a major input from other tissues, often from more than one trigeminal division (Sessle, B. J. *et al.*, 1986).



[a] Inputs from teeth were most common for WDR neurons in nucleus caudalis of cats (Sessle, B. J. *et al.*, 1986).

Figure 1 Interactions affecting dental neuronal function. ATP, adenosine triphosphate; LTM, low-threshold mechanoreceptor; NS, nociceptive specific; WDR, wide-dynamic neuron. Target Neurons: reprinted from Pain, 27, Sessele, B. J., Hu J. W., Amano, N., and Zhong, G., Convergence of cutaneous, tooth pulp, visceral, neck and muscle afferents onto nociceptive and non-nociceptive neurons in trigeminal subnucleus caudalis (medullary dorsal horn) and its implications for referred pain, 219–235, Copyright 1986, with permission from The International Association for the Study of Pain.

Most tooth pain perceptions are acute, and they derive from activation of neurons in nucleus caudalis, although rostral trigeminal nuclei are also involved, and there are other connection sites such as the paratrigeminal nucleus and reticular formation (Sessle, B. J., 2000; 2005).

Human studies show three kinds of evoked sensation from dental nerves: prepain, sharp pain, and dull ache. The first two depend on activation of fast A-β and A-δ-fibers and the latter involves polymodal capsaicin-sensitive slow A-δ and C-fibers (Närhi, M. V. O. *et al.*, 1996; Ikeda, H. *et al.*, 1997), some of which express neuropeptide receptors for autocrine modulation (Suzuki, H. *et al.*, 2002). Each of our teeth is innervated by many hundreds of highly branched trigeminal neurons, and the density of sensory nerve endings in coronal pulp and inner dentin is enormous (Figure 2). However, most intradental neural activity involves unperceived neural efferent functions or reflexes, such as vasodilatation by neuropeptides from sensory fibers that is counterbalanced by sympathetic-mediated vasoconstriction (Figure 3; Olgart, L. 1996; Fristad, I. *et al.*, 1997; Berggreen, E. and Heyeraas, K. J., 2000). Touch sensations during chewing come from Ruffini mechanoreceptors in the periodontal ligament outside the roots, while unconscious aspects of jaw reflexes involve intradental mechanoreceptive A-fibers and the periodontal endings of mesencephalic trigeminal neurons (Dong, W. K. *et al.*, 1993). Dental neurons can express a variety of ionotropic receptors (e.g., TRP-V1, TRP-V2, $P2X_3$, ASIC), metabotropic receptors (BK-1, BK-2, NK1-3, TrkA), ion channels, receptors for neuropeptides, neurotrophins, and opioid peptides that sensitize, inhibit, or modulate sensory neurons (Hu, J. W., 2004), and even immune regulators (Wadachi, R. and Hargreaves, K. M., 2006). The regulation of the pulpal milieu and the quality of tooth pain vary in relation to those activating and modulating systems.

Many dental nerve endings form close appositions with the odontoblasts (Figures 2(a) and 2(b)), while others end freely in pulp and dentin. Neuro-odontoblast interactions are not fully understood, and may involve odontoblast support for the free sensory endings, modulation of sensory activity, and/or specific sensory activity. The lack of synaptic contacts or gap

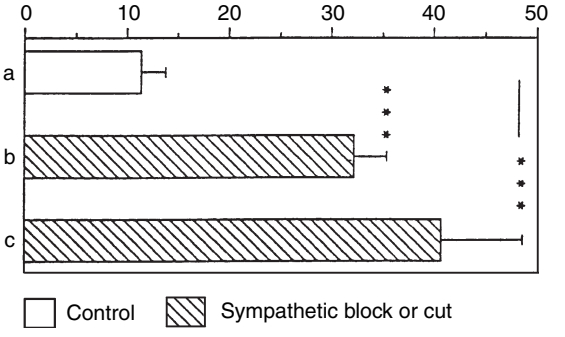


Figure 3 Laser Doppler demonstration of sensory nerve-mediated increased blood flow in rat incisor pulp after α-adrenergic block (b) or sympathectomy (c) compared to intact blood flow (a). All teeth received brief bipolar electrical stimulation of the intact tooth crown. Reproduced from Olgart, L. and Kerezoudis, N. P. 1994. Nerve–pulp interactions. Arch. Oral Biol. 39, 47S–54S, with permission.

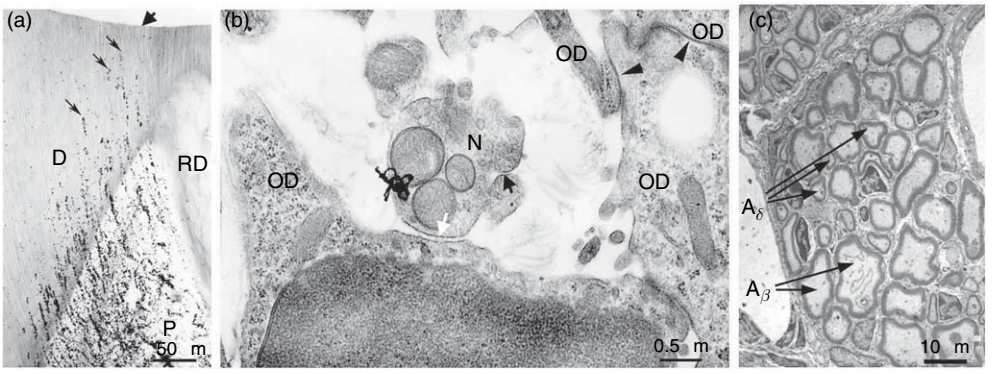

Figure 2 (a) Sensory endings in pulp (P) and dentin (D) (thin arrows) are shown by autoradiography of axonally transported ^{3}H-protein in adult rat molars. They avoid reparative dentin (RD) but come close to surface of tooth (wide arrow). Reprinted from Byers, M.R. 1984. Dental sensory receptors. Int. Rev. Neurobiol. 25, 39–94. (b) Electron microscopic autoradiography showed that transported ^{3}H-proteins (black coiled silver grain) are confined to sensory endings (N). Odontoblasts (OD) are connected by numerous gap junctions (arrowheads). A special apposition separates OD and N (white arrow). Reproduced from Byers, M. R. 1977. Fine structure of trigeminal receptors in rat molars. In: Pain in the Trigeminal Region (*eds*. D. J. Anderson and B. Matthews), pp. 13–24, with permission from Elsevier. (c) Mouse molar root nerves include A-β fibers that exceed 6 μm in diameter and several sizes of A-δ axons.

junctions between odontoblasts and nerves suggests a supportive role. However, demonstrations of neural-like ion channels (Guo, L. and Davidson, R. M., 1998) and TREK-1, a mechanosensitive potassium channel, in odontoblasts (Magloire, H. *et al.*, 2003) show that they are excitable and mechanosensitive. They also attract sensory nerves (Maurin, J. C. *et al.*, 2004) and express neurotrophin factors and receptors in developing, adult, and injured teeth (Fried, K. *et al.*, 2000; Woodnutt, D. A. *et al.*, 2000). It is still not clear whether odontoblast excitability directly affects tooth pain or just allows those cells to monitor dentinogenic requirements.

5.34.2.2 Inflammatory Tooth Pain

When pulp or periapex are inflamed, there are local cellular changes, nerve sprouting, peripheral and central sensitization, and neurochemical plasticity that alter the quality of tooth pain perceptions (Hargreaves, K. M., 2002; Hu, J. W., 2004). Many of the events in inflamed teeth are typical of any inflammation, but there are unusual nerve-sprouting reactions near the pulpitis, and those either subside if healing occurs, or they persist for months or years when lesions escape into the periapical region (Figures 4(a) and 4(b); Byers, M. R. and Närhi, M. V. O., 1999). Important changes occur in dental neuronal satellite cell glia (Figure 4(c)) when inflammation continues in teeth, such as expression of glial fibrillary acidic protein (Stephenson, J. L. and Byers, M. R., 1995). Specialized vascular reactions also occur (Olgart, L., 1996). Recording from individual fibers shows that there are expansions of receptive fields of the A-fiber afferents after 1–2 weeks of inflammation (Figure 5), that would further affect sensitization in the central neurons.

5.34.2.3 Dental Neuropathic Pain

Teeth are major players in referred orofacial pain, either as the source or the referral site, and that situation can lead to unnecessary multiple extractions. Teeth can also exhibit neuropathic symptoms such as hyperalgesia, allodynia, and spontaneous pain (Truelove, E., 2004; Lavigne, G. *et al.*, 2004). A principal mechanism for atypical odontalgia or dental neuropathic pain is the extensive convergence of inputs onto brainstem neurons from a wide area, often involving multiple trigeminal divisions and a variety of tissues (Sessle, B. J., 2000; 2005), and glial actions also affect pain quality (Xie, Y. F. *et al.*, 2006).

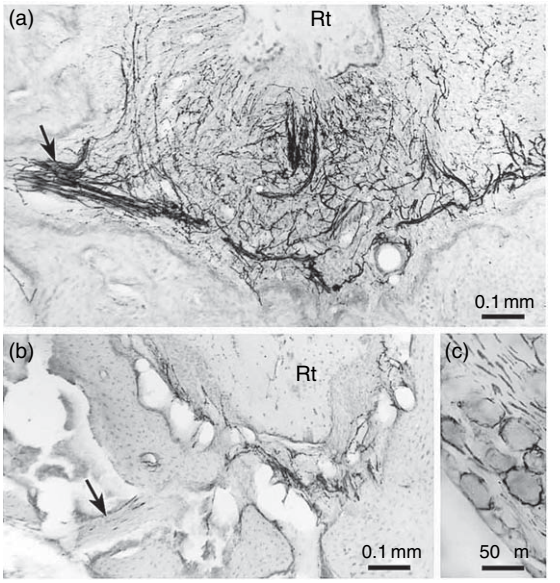

Figure 4 (a, b) Several weeks after tooth injury the lesion has destroyed the pulp and emerged from the root (Rt) into periapical tissue, where there is intense sprouting and immunoreactivity for calcitonin gene-related peptide (CGRP) nerve fibers compared to a normal molar (b). Arrows indicate sensory nerve in alveolar canal. (c) Satellite cells surrounding trigeminal cell bodies are shown by immunocytochemistry to express glial fibrillary acidic protein (black rings) after molar injury in adult rats. (a, b) Reproduced from Kimberly, C. L. and Byers, M. R. 1988. Inflammation of rat molar pulp and periodontium causes increased calcitonin gene-related peptide and axonal sprouting. Anat. Rec. 222, 289–300, with permission.

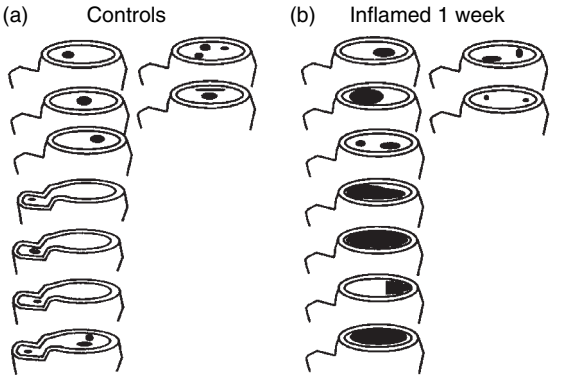

Figure 5 Receptive fields (black patches) for individual A-fibers were larger in dog teeth after 1 week of induced pulpitis compared to control teeth. Reproduced from Närhi, M. V. O., Yamamoto, H., and Ngassapa, D. 1996. Function of Intradental Nociceptors in Normal and Inflamed Teeth. In: Dentin/Pulp Complex (*eds*. M. Shimono, T. Maeda, H. Suda, and K. Takahashi), pp. 136–140. Quintessence Publishing Co, Inc., with permission.

5.34.3 Tooth Pain: Diagnosis and Management

Dentists routinely use evoked acute pain to diagnose tooth pathology, pulp vitality, and treatment (Bender, I. B., 2000). Dental procedures such as orthodontia or root canal treatment cause transient pain that usually decreases within a few days, as the local inflammation subsides, especially with nonsteroidal anti-inflammatory treatment (Dionne, R. A. and Berthold, C. W., 2001). However, pain can persist weeks, months, or years, especially in individuals who have had long-term tooth pain or other chronic pain (Bender, I. B., 2000; Truelove, E., 2004). Tooth pain can expand to a wide area, making it difficult to locate the pathology. Competition from a second pain source can narrow the site to just one tooth, at least for a few minutes to aid diagnosis (Figure 6). This diffuse noxious inhibition implies substantial changes in central physiology for the widely dispersed tooth pains

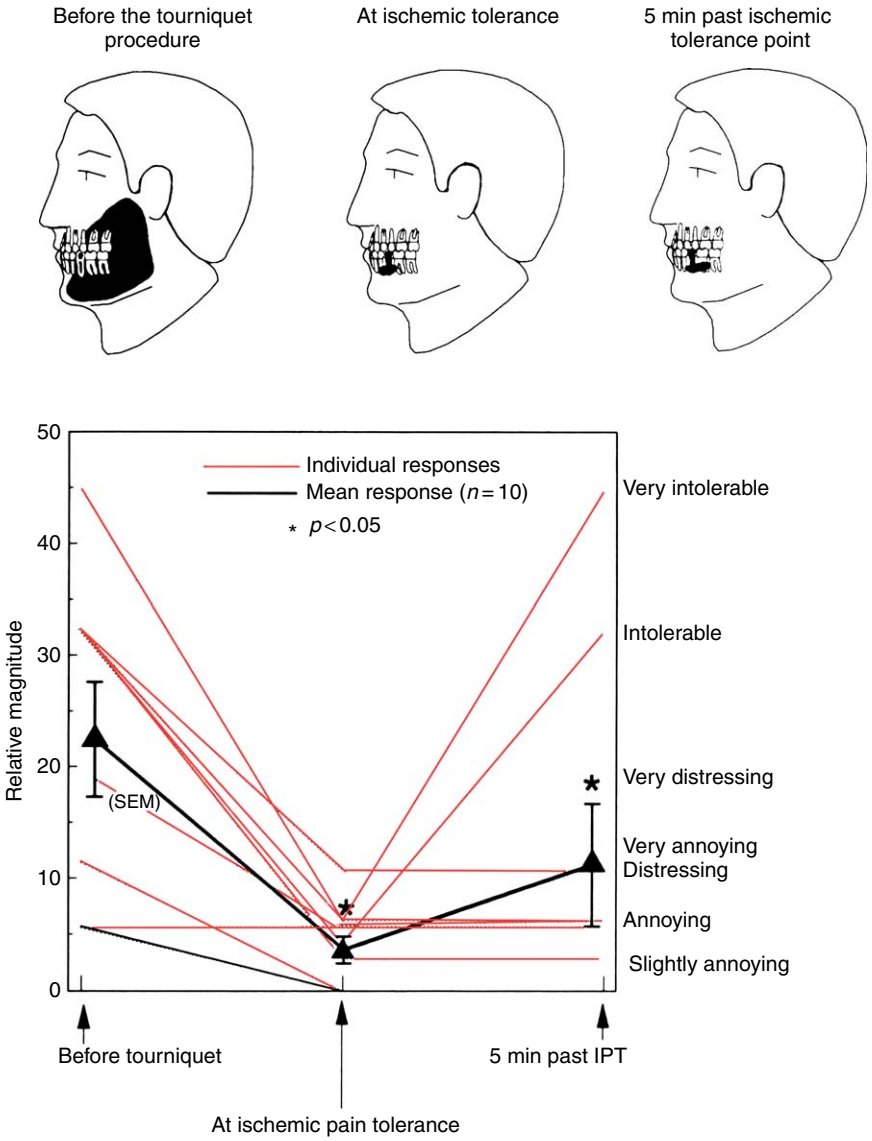

Figure 6 Prior to tourniquet-evoked arm pain, the area of dental pain was large. After maximal arm pain, the tooth pain area was reduced to an individual tooth. By 5 min later, the pain was still focused although the pain intensity (red lines) was returning to prestimulus levels. IPT, ischemic pain tolerance. Reprinted from Pain, 57, Sigurdsson, A. and Maxiner, W., Effects of experimental and clinical noxious counterirritants on pain perception, 265–275, Copyright 1994, with permission from The International Association for the Study of Pain.

(Sessle, B. J., 2005), though important changes in neural sodium channels occur in painful teeth (Renton, T. *et al.*, 2005; Henry, M. A. and Hargreaves, K. M., 2007) offering possible pharmacologic therapeutic targets.

5.34.4 Conclusions

Unusual features of tooth pain include: (1) difficulty locating the source of pain; (2) intense pain from stimulation of dentin; (3) hypersensitive dentin after loss of its protective enamel or periodontal covering, with concomitant pulpitis; (4) special neuro-pulpal interactions; (5) silent pulpal inflammation that only becomes painful when it invades periapical tissues; (6) the hot tooth problem, in which an inflamed painful tooth becomes difficult to anesthetize, even when the rest of the jaw is numb; and (7) referred pain. It is, perhaps, surprising that prolonged tooth pain is unusual, given the huge number of dental procedures every day that can cause tooth, nerve, or bone damage (i.e., dental implants that screw into the jaw, third molar extractions, delicate access for anesthetic injections to reach bone-encased nerves, root canals that remove pulp to eliminate infection). The keys to prevention of debilitating chronic tooth pain include avoiding nerve damage in the jaw, and removal of infected pulp (Bender, I. B., 2000; Hargreaves, K. M., 2002; Hu, J. W., 2004; Truelove, E., 2004; Sessle, B. J., 2005; Henry, M. A. and Hargreaves, K. M., 2007).

Glossary

anterograde tracing Staining of axonal terminal arborizations with a substance (tracer) picked up by the neuronal soma and dendrites and transported through the axon up to its terminal structures.

antidromic activation Evoking neuronal spikes by electric activation of the axon terminal field.

antinociceptive action A neuronal effect that results in decrease of responses to pain

and inhibiton of neurons driven by nociceptive input.

ascending pathway Neuronal tract that conveys input from caudal to rostral areas along the spinal cord and brain.

contralateral pathway Pathway connecting gray matter regions (nuclei) located in opposite sides of the spinal cord or brain.

dendrites The branch units of a dendritic arbor.

dendritic arbor The receptive area of a neuron, organized from the perikarya as the ramifying branches of a tree.

dendritic spines Small protrusions of the dendritic surface that more often appear as a knob connected to the dendritic shaft by a short pedicle.

electrophysiological recording Recording of changes in the membrane potential or current in a neuron.

facilitatory loop Neuronal circuit playing a positive feedback action so that neuronal activity is enhanced.

fiber decussation Crossing of axons from one side to the other side of the spinal cord or the brain.

high-threshold neurons Neurons responsive solely to stimuli of high intensity (noxious).

ipsilateral pathway Pathway connecting gray matter regions (nuclei) located in the same side of the spinal cord or brain.

low-threshold neurons Neurons responsive solely to stimuli of low intensity (innocuous).

neuronal soma The central area of a neuron where the nucleus and most organelles are located.

neurotransmitters Molecules that functionally connect neurons at synapses by being delivered by the presynaptic element upon depolarization and acting upon ligand-gated receptors at the postsynaptic element.

nociresponsive Driven by the arrival of nociceptive input.

noxious stimulation Presentation of stimuli that represent a potential or effective aggression to a peripheral tissue.

pain inhibitory center Region in the central nervous system whose stimulation results in pain depression.

primary sensory neurons Neurons that convey input from the periphery to the central nervous system.

receptive field of a neuron The peripheral area whose stimulation elicits neuronal responses.

retrograde tracing Staining of the neuronal soma and dendritic arbors with a substance (tracer) picked up by the respective axonal boutons and transported back through the axon.

second-order neurons Neurons that transmit input from primary sensory neurons to higher order processing centers.

somatotopy Structural arrangement that correlates topographic organization at different sites, either at the periphery or in the central nervous system.

spinofugal transmission Input transmission away from the spinal cord.

target Area where the axon terminal arborization of a neuron is distributed.

transmitter receptors Plasma membrane molecules which, upon activation by a ligand (neurotransmitter), open ionic channels inducing alteration in the membrane potential.

wide dynamic-range neurons Neurons responsive to stimuli of graded intensities, from innocuous to noxious, but more intensively at the noxious range.

5.35.1 Introduction

5.35.1.1 Defining Nociceptive Ascending Pathways

Nociceptive information traveling from the periphery in primary sensory neurons is transmitted to second-order neurons located at the spinal cord and cranial sensory nuclei. From this first relay, various pathways distribute nociceptive input through higher processing centers so that pain is ultimately perceived in its multiple dimensions and adequate adaptive responses are generated. These ascending pathways are believed to terminate in the cortex with one or several relay stations in their way, although for most of the tracts, studies demonstrating that the intervening neurons are indeed serially connected from the spinal cord to the cortex are missing. The term 'nociceptive ascending pathways' is thus normally used in

a restricted sense, to designate the neuronal tracts that connect the spinal cord with supraspinal regions, each pathway being named from the brain area at which it terminates.

The nociceptive nature of a pathway is classically demonstrated by recording responses to noxious stimuli from spinal neurons antidromically activated from the target (Perl, E. R. and Whitlock, D. G. 1961; Dilly, P. N. *et al.*, 1968). More recently, detection of molecular markers of nociceptive activation (Hunt, S. P. *et al.*, 1987) in conjunction with retrograde tracing has been largely used. By revealing large populations of putative nociceptive neurons, such a procedure allows an easy characterization of the location and morphology of neurons projecting in each pathway, and is particularly valuable to uncover varying population activation patterns as a function of stimulation conditions (Lima, D., 1998).

The structural features that best describe a pathway are the topographic and morphofunctional characteristics of the spinal neurons involved and the area of termination of their axons. Studies addressing the morphology of spinal projecting neurons are particularly few and mainly related to lamina I. One of the reasons for the restricted use of this kind of evaluation is the lack of systematic models of classification of spinal neurons apart from laminae I (Gobel, S. 1978a; Lima, D. and Coimbra, A., 1983; 1986) and II (Gobel, S., 1978b). Recent studies, however, call our attention to the importance of neuronal morphology, in particular, dendritic geometry, in defining the signal-processing properties of neurons (Prescott, S. A. and De Koninck, Y. 2002; Szucs, P. *et al.*, 2003; Mainen, Z. F. and Sejnowski, T. J. 2006), which justify taking these aspects into account when addressing the anatamophysiology of a pathway.

The multitude of ascending nociceptive pathways, together with the subtleness of the anatomical and physiological features that separate them as to their origin at the spinal cord, makes it difficult to attribute a particular functional meaning to each one. A tentative way of unraveling the role of each pathway in nociceptive processing has been the elucidation of the connections established by the target.

5.35.1.2 The Spinothalamic System

The classical view of the ascending nociceptive system puts particular emphasis on the dual distribution of nociceptive input through a lateral pathway responsible for sharp, well-localized short lasting pain, and a medial pathway responsible for diffuse, poorly localized persisting pain (Figure 1). From the spinal cord, nociceptive input is conveyed both to the posterior lateral sensory nuclei of the thalamus, in the lateral or neospinothalamic pathway (Bowsher, D. 1957; Mehler, W. R. 1957; Willis, W. D. *et al.*, 1974; Giesler, G. J. *et al.*, 1976) and to medial thalamic nuclei, in the medial or paleospinothalamic pathway (Mehler, W. R. *et al.*, 1956; Bowsher, D. 1957; Mehler,

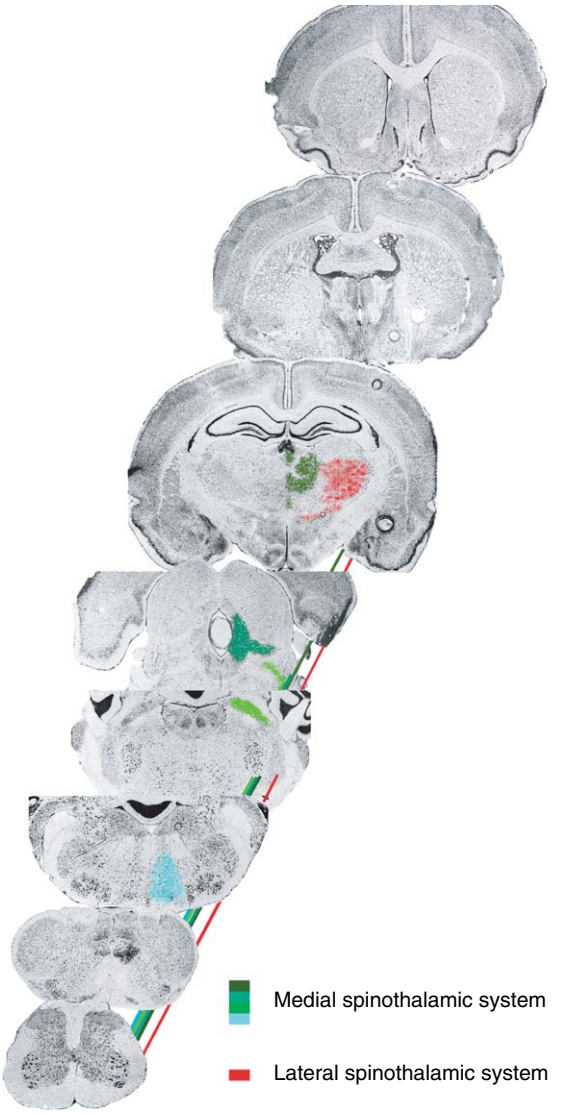

Figure 1 Diagrammatic representation of the areas of termination of the lateral spinothalamic pathway and the medial spinothalamic pathway, and the spinoreticular pathways that serve as relays in the medial spinothalamic system. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

W. R. 1957; Giesler, G. J. *et al*., 1981b). While the first is monosynaptic, made up of spinal neurons projecting directly to the thalamus (Trevino, D. L. and Carstens, E. 1975; Willis, W. D. *et al*., 1979; Giesler, G. J. *et al*., 1979a), the second is either monosynaptic or polysynaptic with a variable number of relays along the brainstem (Johnson, F. H. 1954; Mehler, W. R. *et al*., 1956; Rossi, G. F. and Brodal, A. 1957; Bowsher, D. 1957; Carstens, E. and Trevino, D. L. 1978b; Willis, W. D. *et al*., 1979; Giesler, G. J. *et al*., 1979a).

The lateral spinothalamic pathway was proposed to be involved in the discriminative aspects of pain (Bowsher, D. 1957; Melzack, R. and Casey, K. L. 1968) based on early studies on the perception deficits resulting from lesions of lateral thalamic nuclei (Dejerine, J. and Roussy, G. 1906; Melzack, R. and Casey, K. L. 1968). This was later supported by studies showing that both spinal and thalamic neurons of the lateral spinothalamic pathway present small receptive fields (Giesler, G. J. *et al*., 1981b; Willis, W. D. 1988), are capable of encoding the extent of the stimulated area and the intensity of the stimulus(Kenshalo, D. R., Jr. *et al*., 1979; Peschanski, M. *et al*., 1980; Guilbaud, G. *et al*., 1985; Willis, W. D. 1988; Guilbaud, G. and Kayser, V. 1988), and terminate following a somatotopic pattern in the thalamus and cortex respectively (Whitsel, B. L. *et al*., 1978; Boivie, J. 1979). The medial spinothalamic pathway was claimed to deal with the affective and volitive aspects of pain (Bowsher, D. 1957; Melzack, R. and Casey, K. L. 1968) based on similar behavioral studies on human and experimental animals suffering from lesions of various brainstem or thalamic areas (Dejerine, J. and Roussy, G. 1906; Walker, A. E. 1942b; Hécaen, H. *et al*., 1949). This view was again supported by studies revealing that spinal and thalamic neurons of the medial pathway present large receptive fields, responses unrelated to stimulus intensity (Giesler, G. J. *et al*., 1981b; Guilbaud, G. *et al*., 1985) and no topographical arrangement of their axonal terminal arborizations in both the thalamus (Boivie, J. 1979) and cortex (Morison, R. S. and Dempsey, E. W. 1942; Jones, E. G. and Leavitt, R. Y. 1974).

In the last decades, the use of very sensitive electrophysiological and tracing techniques revealed a wide variety of brainstem loci capable of contributing as relays to the medial spinothalamic system (reviewed by (Lima, D., 1997), and uncovered ascending pathways that bypass the thalamus to terminate directly on telencephalic areas, including the cortex (Cliffer, K. D. *et al*., 1991). In this chapter, the various pathways involved in the spinofugal transmission of nociceptive input will be referred following a caudorostral sequence.

5.35.2 Spinocervical Pathway

The spinocervical pathway is one of the ascending putative nociceptive pathways uncovered the earliest, based on its capacity to activate cortical sensory areas (Catalano, J. V. and Lamarche, G., 1957; Mark, R. F. and Steiner, J., 1958) and on the finding that neurons of the lateral cervical nucleus (LCN) project to the ventrobasal complex of the thalamus (Ha, H. and Liu, C. N., 1966; Craig, A. D. and Burton, H., 1979; Baker, M. L. and Giesler, G. J., 1985; Giesler, G. J., *et al*., 1987). It has been claimed, however, to be mostly dedicated to the processing of tactile, hair movement input (Lundberg, A. and Oscarsson, O., 1961; Taub, A. and Bishop, P. O., 1965) and be mainly represented in carnivores (Flink, R. and Westman, J., 1986). The identification of a neuronal column continuing the lateral cervical nucleus caudally along the entire length of the cord (the lateral spinal nucleus), together with the finding that their neurons also send projections to the thalamus as well as to many other brain areas (see ahead), raised the possibility that the lateral cervical nucleus is part of a more extensive spinal neuronal aggregation lying within the dorsolateral fasciculus, which serves as a relay in various ascending nociceptive pathways. Nonetheless, differences in the morphology and response properties of lateral cervical and lateral spinal neurons (Giesler, G. J. *et al*., 1979b; Menétrey, D. *et al*., 1980) point to a specific role of the former in conveying ascending input to the lateral thalamus.

5.35.2.1 Spinal Laminae of Origin and Sites of Termination

Neurons projecting to the lateral cervical nucleus are mainly located in the ipsilateral spinal cord at lamina IV (Figure 2) (Bryan, R. N. *et al*., 1973; Craig, A. D., 1976; Brown, A. G. *et al*., 1976; Cervero, F. *et al*., 1977; Brown, A. G. *et al*., 1977; Craig, A. D., 1978; Brown, A. G. *et al*., 1980a; Baker, M. L. and Giesler, G. J., 1984), where they amount to 60% of the entire population, followed by lamina III (10%) (Brown, A. G. *et al*., 1980a). Scattered neurons are present in other laminae such as laminae I, V, VI, and VII (Craig, A. D., 1976; Craig, A. D., 1978; Brown, A. G. *et al*., 1980a;

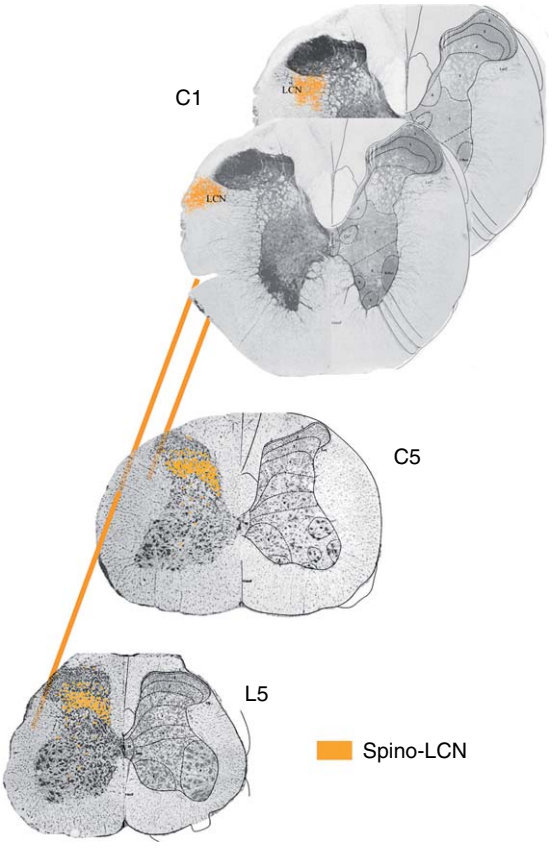

Figure 2 Diagram representing the spinal laminae of origin, ascendingb course in the spinal cord, and areas of termination of the spino-LCN pathway. Note the somatotopic arrangement of the axon terminal fields according to their rostrocaudal origin. (in this figure and figures 3, 7, 10, 12, 13, 15, 17, 19, 21 and 24, the left side is ipsilateral to the side of arrival of peripheral input) Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

Baker, M. L. and Giesler, G. J., 1984). Axonal terminals are somatotopically organized, fibers originated in caudal levels terminating in the dorsolateral aspect of the caudal portion of the lateral cervical nucleus, and fibers originated in rostral levels in the medial aspect of its rostral portion (Figure 2) (Svensson, B. A. *et al.*, 1985).

5.35.2.2 Structural Types of Neurons Involved

Neurons targeting the lateral cervical nucleus are commonly described as small-sized (10–20 μm) (Craig, A. D., 1978; Baker, M. L. and Giesler, G. J., 1984), but neurons with large round soma have also been observed in lamina IV (Craig, A. D., 1978). They present dorsally oriented dendrites (Brown, A. G. *et al.*, 1976; Jankowska, E. *et al.*, 1976; Brown, A. G. *et al.*, 1977; Craig, A. D., 1978; Brown, A. G. *et al.*, 1980b), which extend rostrocaudally for up to 2000 μm without penetrating lamina II (Brown, A. G. *et al.*, 1977; Brown, A. G. *et al.*, 1980b).

5.35.2.3 Spinal Location of Ascending Fibers

Spinal axons targeting the lateral cervical nucleus course ipsilaterally in the dorsal part of the lateral funiculus (Figure 2) (Brown, A. G. *et al.*, 1977; Baker, M. L. and Giesler, G. J., 1984; Giesler, G. J. *et al.*, 1988). According to Ha and Liu (Ha, H. and Liu, C. N., 1966), they are often collaterals of fibers coursing to more rostral levels.

5.35.2.4 Response properties

Nociceptive neurons at the origin of the spinocervical pathway present background activity in bursts (Brown, A. G. and Franz, D. N., 1969). They are activated by Aβ, Aδ, and C primary afferent fibers (Taub, A. and Bishop, P. O., 1965), A fibers exciting the entire neuronal population either alone (29%) or in convergence with C fibers (71%) (Brown, A. G. *et al.*, 1975). They belong in the low-threshold (LT), wide-dynamic range (WDR) and high-threshold (NS) classes (Brown, A. G. and Franz, D. N., 1969; Bryan, R. N. *et al.*, 1973; Bryan, R. N. *et al.*, 1974; Cervero, F. *et al.*, 1977; Downie, J. W. *et al.*, 1988). Neurons receiving high-threshold input were reported to make up between 60% and 86% of the entire projecting population (Cervero, F. *et al.*, 1977; Kajander, K. C. and Giesler, G. J., 1987). High-threshold input is generated either by pressure, pinch, heat, or cold (Brown, A. G. and Franz, D. N., 1969; Bryan, R. N. *et al.*, 1973; Bryan, R. N. *et al.*, 1974; Cervero, F. *et al.*, 1977; Downie, J. W. *et al.*, 1988), while low-threshold input is mainly originated in hair follicle afferent receptors (Brown, A. G. and Franz, D. N., 1969). Receptive fields are small and located in hairy as well as glabrous skin (Bryan, R. N. *et al.*, 1974; Kunze, W. A. A. *et al.*, 1987; Downie, J. W. *et al.*, 1988). They are organized somatotopically so that cells located more laterally have receptive fields in the dorsal surface of the body and cells located more medially in the ventral surface (Bryan, R. N. *et al.*, 1973; Bryan, R. N. *et al.*, 1974; Brown, A. G. *et al.*,

1980a). Inhibitory receptive fields were described adjacent to the excitatory receptive field (Brown, A. G. *et al.*, 1987; Short, A. D. *et al.*, 1990) or in the contralateral limb (Brown, A. G. and Franz, D. N., 1969). Natural stimuli causing neuronal inhibition include hair movement, pressure, and squeezing (Brown, A. G. and Franz, D. N., 1969; Brown, A. G. *et al.*, 1987; Short, A. D. *et al.*, 1990). Convergence of cutaneous and deep tissues input has been reported (Kniffki, K. D. *et al.*, 1977; Hamann, W. C. *et al.*, 1978; Harrison, P. J. and Jankowska, E., 1984). Only cells responsive to both hair movement and skin pressure were shown to receive group III and IV muscle afferent input (Hamann, W. C. *et al.* 1978). Muscle and joint primary afferent activation can also elicit neuronal inhibition (Hamann, W. C. *et al.* 1978; Harrison, P. J. and Jankowska, E. 1984).

5.35.2.5 Pathways Driven at the Target

Axons from neurons in the lateral cervical nucleus join the medial lemniscus contralaterally and terminate in the midbrain, the ventral posterial lateral nucleus (VPL), and the posterior complex (PO) of the thalamus (Ha, H. and Liu, C. N., 1966). In the midbrain, the lateral part of the periaqueductal gray (PAG) receives afferents from the lateral two-thirds of the lateral cervical nucleus (Mouton, L. J. and Holstege, G., 2000; Mouton, L. J. *et al.*, 2004). In the VPL, fibers ascending from the lateral cervical nucleus are topographically arranged so that those originated in its dorsolateral portion terminate in the VPL, *pars lateralis*, and those originated in its ventromedial portion terminate in the VPL, *pars medialis* (Craig, A. D. and Burton, H., 1979).

5.35.3 Spinobulbar Pathways

Most spinobulbar pathways were uncovered relatively recently and are not as thoroughly studied as the more rostrally terminating pathways such as the spinomesencephalic and the spinothalamic. With the exception of the rostral ventromedial medulla (RVM), the majority of the studies dealing with spinobulbar pathways were performed in the rat. An anecdotic study addressing the spinal pathways terminating in the caudal medulla of the pigeon (Galhardo, V. *et al.*, 2000), however, reveals remarkable similarities with the rat, pointing to a high degree of phylogenetic conservation.

5.35.3.1 Ventrolateral Reticular Formation

5.35.3.1.1 Spinal laminae of origin and sites of termination

Spinal cells projecting to the caudal ventrolateral reticular formation (VLM) are distributed through laminae I, II, IV–VII, VIII, X, and the lateral spinal nucleus (Figure 3) (Menétrey, D. *et al.*, 1983; Menétrey, D. *et al.*, 1984; Leah, J. *et al.*, 1988; Lima, D. *et al.*, 1991; Galhardo, V. *et al.*, 2000). Projections were first described to be mainly contralateral (Menétrey, D. *et al.*, 1983; Menétrey, D. *et al.*, 1984; Thies, R., 1985), but an important ipsilateral component was revealed by the use of more sensitive retrograde tracers (Menétrey, D. *et al.*, 1982; Lima, D. *et al.*, 1991; Menétrey, D. *et al.*, 1992b; Galhardo, V. *et al.*, 2000). There is, however, a large variability in the proportion of cells labeled in each spinal side, particularly with respect to cells located in the superficial dorsal horn. Both ipsilateral and contralateral predominance have been observed, in a few cases in the same animal at different rostrocaudal levels (Lima, D. *et al.*, 1991). The occurrence of subtle differences in the area of termination of each spinal side along the cord length was proposed as a tentative explanation, but experiments designed to clarify a putative somatotopic arrangement are missing.

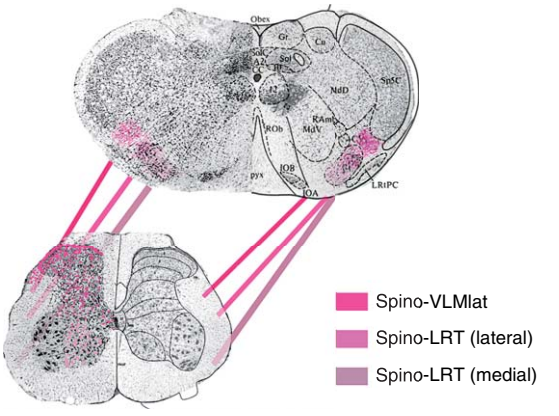

Figure 3 Diagram representing the spinal laminae of origin, ascending course in the spinal cord, and areas of termination of the spino-VLM pathway. Note the contribution of lamina II neurons. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

Spino-VLM axons appear to give axonal collaterals to various sites within the brainstem (Thies, R., 1985), such as the parabrachial nuclei (PBN) and the PAG (Spike, R. C. *et al.*, 2003).

The use of discrete injections, which became possible with the advent of particularly sensitive tracing methods, clearly demonstrated that the spino-VLM system is composed of three pathways originating in three distinct spinal regions (Figure 3).

The pathway originating in the superficial dorsal horn (laminae I–III) and lateral spinal nucleus was observed in the rat (Lima, D. and Coimbra, A., 1991; Tavares, I. *et al.*, 1993), cat, and monkey (Craig, A. D., 1995) to terminate in the lateral-most portion of the VLM (VLMlat), in between the spinal trigeminal nucleus and the ventral tip of the lateral reticular nucleus (LRt). The pathways originating in the deep dorsal horn (laminae IV–VI) and intermediate/ventral horn (laminae VII and X) terminate, respectively, in the lateral half and the medial half of the LRt (Lima, D. *et al.*, 1991).

A curious aspect of the spino-VLMlat projection is the participation of a large amount of cells of the substantia gelatinosa, or lamina II (Figure 4) (Lima, D. *et al.*, 1991; Lima, D. and Coimbra, A., 1991), an area that was not shown to participate significantly in any other ascending pathway and is therefore usually taken as involved in nociceptive modulatory local or propriospinal circuits (see Chapter Spinal Cord Physiology of Nociception). Lamina II neurons project, together with neurons in lamina I and the lateral spinal nucleus, to the VLMlat (Figure 3), contributing to almost one-third of the entire spinal-VLMlat projection in the cervical enlargement, and to one-fifth in the lumbar enlargement.

(Lima, D. and Coimbra, A., 1991). There are still no clues on the physiological meaning of this unique lamina II projection to the VLMlat. Studies aimed at clarifying whether these cells participate in inhibitory circuits similar to those described in the superficial dorsal horn failed to reveal GABA content in these neurons (Tavares, I. and Lima, D., 2002).

5.35.3.1.2 Structural types of neurons involved

Lamina I neurons projecting in the spino-VLM pathway were characterized in the rat, based on the comparison of the structural features of neurons retrogradely labeled with CTb at various spinal cord levels in the three anatomical planes (Lima, D. *et al.*, 1991). In the rat, as in the pigeon (Galhardo, V. *et al.*, 2000), spino-VLM neurons belong in three (fusiform,

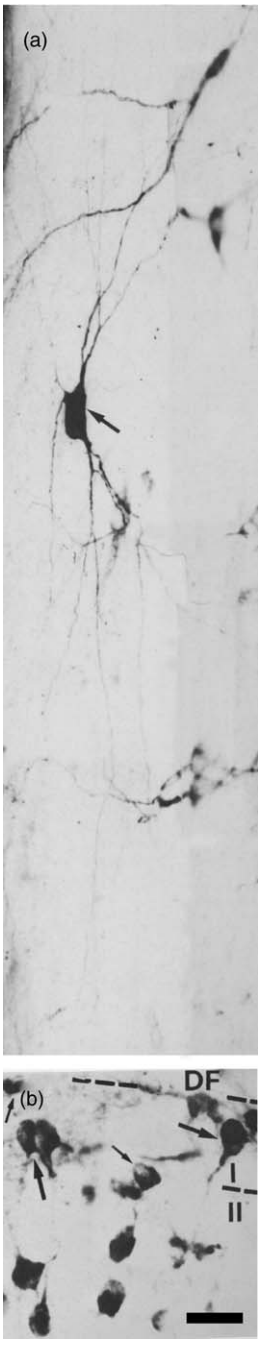

Figure 4 Superficial dorsal horn neurons labeled retrogradely with cholera toxin subunit B (CTb) from the VLMlat. (a) Lamina I neuron of the fusiform type, subtype B, in horizontal view. (b) Lamina I fusiform neurons and lamina II neurons in transverse view. Note the ventrally oriented dendrites of fusiform B neurons (large arrows in (b)). DF – Dorsal funiculus. Scale bar = 30 μm. Adapted from figure 3 of Lima, D., Mendes-Ribeiro, J. A., and Coimbra, A. 1991. The spino-latero-reticular system of the rat: projections from the superficial dorsal horn and structural characterization of marginal neurons involved. Neuroscience 45, 137–152.

pyramidal, and flattened) of the four structural neuronal groups present in lamina I. The majority (around 80%) are of the fusiform type, a neuronal group whose main characteristic is the strict longitudinal spiny dendritic arbor. Some fusiform neurons present a few dendrites oriented ventrally and penetrating the entire width of lamina II (Figure 4). These neurons, classified as fusiform B by Lima and Coimbra (Lima, D. and Coimbra, A., 1986), represent a large fraction of VLMlat-projecting fusiform cells (20%) when compared to the small contribution of this neuronal subtype (6%) to the entire lamina I fusiform neuronal population (Lima, D. and Coimbra, A., 1986). Curiously, fusiform B neurons could not be observed in other spinofugal pathways. This finding is particularly interesting in the light of the contribution of lamina II neurons to this pathway (Figure 4). It may indicate that neurons of the fusiform B subtype cooperate with lamina II neurons in transmitting to the VLMlat primary input arriving at lamina II. The remaining 20% VLM-projecting lamina I neurons belong to the flattened and pyramidal types in similar amounts. These two cell groups have in common long practically aspiny dendrites coursing horizontally, parallel to the dorsal surface of lamina I. Pyramidal neurons have, in addition, dendrites that ramify inside the white matter overlying lamina I.

VLM-projecting lamina II neurons present ovoid, rostrocaudally elongated dendritic arbors that extend as parasagittal sheets through the entire width of lamina II (Lima, D. and Coimbra, A., 1991), resembling the central and the limiting cells of Ramón y Cajal (Ramón y Cajal, S., 1909).

5.35.3.1.3 Spinal location of ascending fibers

According to the intense fiber staining occurring in the dorsolateral fasciculus after retrograde tracer injections in theVLMlat (Lima, D. *et al.*, 1991), VLM projections from laminae I–III course in the dorsal portion of the lateral funiculus (Figure 3), as is the case of the spinomesencephalic (McMahon, S. B. and Wall, P. D., 1985; Hylden, J. L. K. *et al.*, 1986b) and spinothalamic (Apkarian, A. V. *et al.*, 1985; Apkarian, A. V. and Hodge, C. J., 1989c) pathways.

5.35.3.1.4 Surface receptors

Large numbers of lamina I neurons projecting to the VLM express neurokinin I (NK1) (Figure 5) (Todd, A. J. *et al.*, 2000; Spike, R. C. *et al.*, 2003; Castro, A. R. *et al.*, 2006) and $GABA_B$ receptors (Castro, A. R. *et al.*, 2006), the co-localization of both being relatively frequent (Castro, A. R. *et al.*, 2006).

In addition, 90% of the large deep dorsal horn neurons with dendrites entering superficial laminae and exhibiting the NK1 receptor project to the VLM (Todd, A. J. *et al.*, 2000). Appositions of serotonin (5HT) and noradrenalin-containing axonal boutons upon VLM-projecting lamina I neurons are common (Tavares, I. *et al.*, 1996a; Polgar, E. *et al.*, 2002). Serotoninergic boutons establish symmetrical synaptic contacts and are more abundant upon neurons expressing the NK1 receptor (Polgar, E. *et al.*, 2002).

5.35.3.1.5 Neurotransmitters

As in most ascending pathways conveying nociceptive input, studies addressing the neurochemical content of

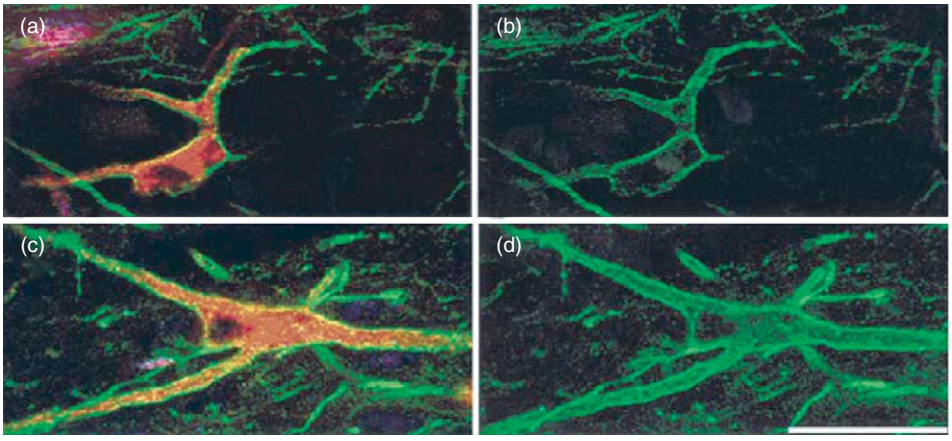

Figure 5 Flattened (a, b) and pyramidal (c, d) lamina I neurons, in horizontal view, retrogradely labeled with cholera toxin subunit B (CTb) from the VLM (red) and immunoreactive for the NK1 receptor (green). Scale bar = 50 μm. Adapted from figure 9 of Spike, R. C., Puskar, Z., Andrew, D., and Todd, A. J. 2003. A quantitative and morphological study of projection neurons in lamina I of the rat lumbar spinal cord. Eur. J. Neurosci. 18, 2433–2448.

the neurons of origin of the spino-VLM pathway have focused on neuropeptides. The exhaustive study of Leah and collaborators (Leah, J. *et al.*, 1988) revealed a relatively large amount of vasoactive intestinal peptide (VIP), bombesin, dynorphin, and substance P-immunoreactive VLM-projecting neurons in the lateral spinal nucleus. A few enkephalin immunoreactive neurons were observed in lamina X. Calbindin is present in particularly large numbers of lumbosacral cells projecting to the VLM-bilaterally, especially within lamina I and the lateral spinal nucleus, but also in lamina X (Menétrey, D. *et al.*, 1992b). Although fusiform neurons in lamina I (Lima, D. *et al.*, 1993) and neurons in lamina II (Todd, A. J. and Spike, R. C., 1993) are known to contain GABA, GABA-immunostaining of neurons retrogradely labeled from the VLM could not be observed (Tavares, I. and Lima, D., 2002).

5.35.3.1.6 Response properties

The response properties of neurons projecting to the ventrolateral reticular formation were studied in the rat (Menétrey, D. *et al.*, 1984) and cat (Thies, R., 1985). A high proportion of VLM-projecting neurons are spontaneously active (Menétrey, D. *et al.*, 1984; Thies, R., 1985). NS neurons make up about half of the entire population of VLM-projecting neurons (Menétrey, D. *et al.*, 1984; Thies, R., 1985). The remaining are either WDR or LT/proprioceptive neurons (Menétrey, D. *et al.*, 1984; Thies, R., 1985). They often present bilateral symmetrical receptive fields as well as cutaneous inhibitory receptive fields (Menétrey, D. *et al.*, 1984). Convergence of cutaneous, visceral, and muscle input is frequently observed (Thies, R., 1985). By monitoring noxious-evoked c-*fos* induction (Tavares, I. *et al.*, 1993), 10% to 20% of VLM-projecting neurons were shown to be activated by heat or mechanical stimulation in laminae I and IIo. In lamina IIi, neurons were activated in fewer numbers and only after thermal stimulation.

5.35.3.1.7 Pathways driven at the target

The VLM projects to several brain areas also receiving nociceptive input from the spinal cord and involved in pain control as well as cardiovascular, endocrine, or limbic functioning. Among these areas stand the RVM; the dorsal reticular nucleus (DRt); the A_5, A_6, and A_7 pontine noradrenergic groups (Tavares, I. *et al.*, 1996b); the hypothalamus (Calaresu, F. R. *et al.*, 1984; Malick, A. *et al.*, 2000); and the central nucleus of the amygdala (Zardettosmith, A. M. and Gray, T. S., 1995). Studies focused on the brainstem showed that the VLMlat is the VLM region that establishes connections with other supraspinal pain inhibitory centers (Tavares, I. *et al.*, 1996b; Cobos, A. *et al.*, 2003), pointing to a role of the superficial dorsal horn-VLMlat pathway in driving the potent descending inhibition that can be elicited upon stimulation of VLM (Gebhart, G. F. and Ossipov, M. H., 1986). At the RVM and the pontine A_5 noradrenergic group, terminal arborizations of VLM axons appose spinal-projecting neurons (Figure 6), indicating that pain control actions from those areas are indeed under the control of the VLM (Tavares, I. *et al.*, 1996b).

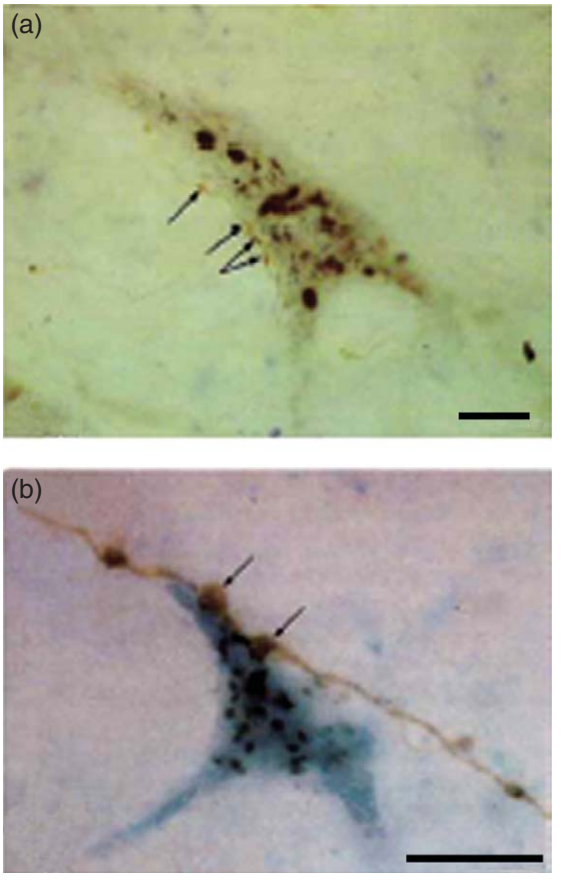

Figure 6 RVM (a) and A_5 (b) neurons retrogradely labeled with cholera toxin subunit B (CTb) from the spinal cord (brown granules) and receiving appositions (arrows) from axonal boutons anterogradely labeled with biotinilated dextran amine (BDA) from the VLM. Neuron in (b) is immunoreactive for dopamine-β-Hydroxylase (DBH; blue). Scale bar = 20 μm. (Adapted from figure 3 of Tavares, I., Lima, D., and Coimbra, A. 1996b. The ventrolateral medulla of the rat is connected with the spinal cord dorsal horn by an indirect descending pathway relayed in the A5 noradrenergic cell group. J. Comp. Neurol. 374, 84–95).

In the A_5, spinal-projecting neurons contacted by VLMlat fibers are noradrenergic (Figure 6) and postsynaptic in asymmetric, putative excitatory synaptic contacts (Tavares, I. *et al.*, 1996b). This was taken as suggestive that the spinal α_2 adrenoreceptor-mediated antinociceptive action triggered in the VLM is dependent on VLMlat activation and relayed in the A_5 group.

The VLM also sends direct descending projections to the spinal cord (Tavares, I. and Lima, D., 1994). Projections to both the superficial and deep dorsal horn originate in the VLMlat (Tavares, I. and Lima, D., 1994). Data from several studies indicate that noradrenaline is not used in the direct VLM-spinal pathway (Westlund, K. N. *et al.*, 1981; Westlund, K. N. *et al.*, 1983; Tavares, I. *et al.*, 1996b). VLMlat axons targeting lamina I make up a reciprocal closed VLM-spino-VLM loop which is entirely excitatory at the VLM level, and both excitatory and inhibitory at the spinal level (Tavares, I. *et al.*, 1998; Tavares, I. and Lima, D., 2002).

The cerebellar connections of the LRt (Cledenin, M. *et al.*, 1974; Parenti, R. *et al.*, 1996), together with the fact that, contrary to the VLMlat, the LRt does not contribute descending projections to the spinal cord dorsal horn (Tavares, I. and Lima, D., 1994), point to a role of the deep dorsal horn/ventral horn-LRt pathways in the control of motor activity in response to pain.

5.35.3.2 Dorsal Reticular Nucleus

5.35.3.2.1 Spinal laminae of origin and sites of termination

The medullary dorsal reticular nucleus (DRt) was first shown in the rat to be the site of termination of an important, mainly ipsilateral, pathway ascending from the spinal cord (Lima, D. and Coimbra, A., 1985; Lima, D., 1990; Villanueva, L. *et al.*, 1991). By the same time, neurons in the DRt were shown to be exclusively or preferentially activated by noxious stimuli from the skin and viscera (Villanueva, L. *et al.*, 1988). The spino-DRt pathway was later uncovered in other species such as the cat, monkey (Craig, A. D., 1995), and pigeon (Galhardo, V. *et al.*, 2000). It is constituted by a dorsal and ventral component differing in the area of termination within the DRt (Figure 7).

The dorsal pathway terminates at the dorsal-most portion of the DRt, immediately above the level of the central canal and surrounding the ventral border of the cuneate nucleus (Almeida, A. *et al.*, 1995; Almeida, A. *et al.*, 2000). It originates from the medial-most part of laminae I–III ipsilaterally, with a marked predominance of lamina I, and from lamina X, bilaterally (Figure 7) (Lima, D., 1990). The ventral pathway terminates ventrally to the area of termination of the dorsal pathway, within both sides of the DRt (Almeida, A. *et al.*, 1995; Almeida, A. *et al.*, 2000).

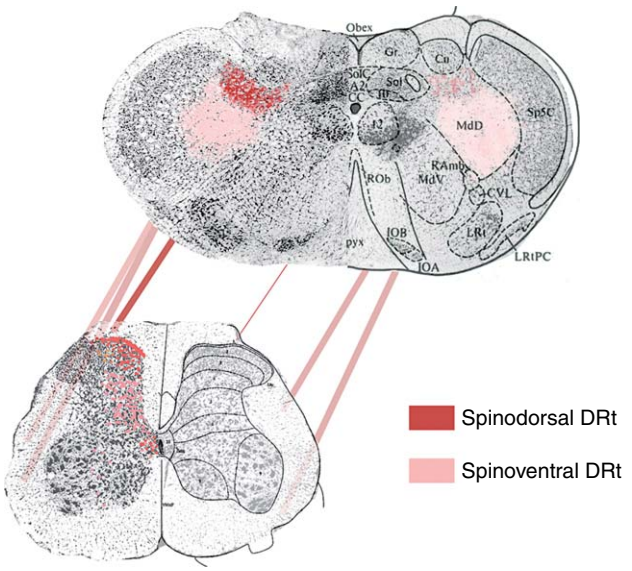

Figure 7 Diagram representing the spinal laminae of origin, ascending course in the spinal cord, and areas of termination of the spino-DRt pathway. Note the preferential medial location of dorsal horn neurons. Fibers of the spinodorsal DRt pathway course in the dorsal funiculus. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

Its cells of origin prevail ipsilaterally in the medial portion of laminae IV–VI, with additional bilateral participation from laminae VII and X (Figure 7) (Lima, D., 1990). Interestingly, retrograde labeling from the superficial or deep dorsal horn demonstrated descending pathways arising, respectively, from the ipsilateral dorsal-most part of the DRt or from both sides of the ventral DRt (Tavares, I. and Lima, D., 1994). The DRt is thus part of two distinct reciprocal loops connecting its dorsal part with the superficial dorsal horn ipsilaterally, and ventral part with the deep dorsal horn bilaterally (Almeida, A. *et al.*, 1993; Almeida, A. *et al.*, 2000).

5.35.3.2.2 Structural types of neurons involved

Lamina I neurons projecting to the dorsal DRt were structurally characterized in the rat based on observations of neurons retrogradely filled with CTb in the three anatomical planes (Lima, D. and Coimbra, A., 1990). As to other spinal laminae, no data have been collected so far. In the rat, about 30% of lamina I neurons projecting to the DRt belong in the pyramidal and flattened types in similar amounts. The remaining 70% are of the multipolar type, a finding particularly curious taking into account that multipolar neurons were not seen to project in other ascending pathways. These cells are rather peculiar due to the typical lamina II crossing of the dendritic arbor, the bush pattern of the highly ramified proximal dendritic branches and the profusion and large variety of dendritic spines (Lima, D. and Coimbra, A., 1986). Another interesting feature of multipolar cells is their preferential location in the medial third of lamina I in the rat (Lima, D. and Coimbra, A., 1983; Lima, D. and Coimbra, A., 1986). The same structural types of lamina I neurons were seen to project to the DRt in the pigeon, although flattened and pyramidal neurons were relatively more abundant in this species (Galhardo, V. *et al.*, 2000).

5.35.3.2.3 Spinal location of ascending fibers

An interesting aspect of the spino-DRt pathway, apparently only shared with the spino-NTS pathway (Gamboa-Esteves, F. O. *et al.*, 2001c), is the course of their axons in the dorsal funiculus. This was first suggested by the dorsal orientation of axonal processes of lamina I neurons labeled retrogradely from the DRt and by comparing retrograde labeling rostrally and caudally to lesions of the dorsal funiculus (Lima, D., 1990). Retrograde labeling was completely abolished in ipsilateral laminae I–III and markedly diminished in the deep dorsal horn at segments caudal to the lesion. Anterograde tracing later revealed that numerous fibers are labeled in the dorsal funiculus after injections in superficial laminae, and in the dorsolateral fasciculus after injections in deep dorsal horn laminae (Almeida, A. *et al.*, 1995). Accordingly, injections in the dorsal funiculus resulted in DRt labeling restricted to its ipsilateral dorsal part, while injections in the dorsolateral fasciculus produced ipsilateral ventral DRt labeling (Almeida, A. *et al.*, 1995). These findings not only confirm a dual ascending tract for the dorsal and ventral DRt pathways, but also indicate that fiber decussation in the ventral pathway takes place near the segment of origin, as in most other pathways.

5.35.3.2.4 Surface receptors

A significant amount of lamina I neurons projecting to the DRt express the NK1 receptor alone (Todd, A. J. *et al.*, 2000; Castro, A. R. *et al.*, 2006) or together with the $GABA_B$ receptor (Castro, A. R. *et al.*, 2006). DRt-projecting neurons expressing only the $GABA_B$ receptor are, however, much more numerous (Castro, A. R. *et al.*, 2006). In laminae III–IV, about 20% of NK1-expressing neurons project to the DRt (Todd, A. J. *et al.*, 2000).

5.35.3.2.5 Neurotransmitters

So far, there are no studies addressing the possible neurotransmitters used in the spino-DRt pathway. Nevertheless, it is interesting to note that, although immunoreactions for GABA revealed immunostaining of lamina I neurons of the multipolar type, (Lima, D. *et al.*, 1993), even in the early 2000s, GABA could not be detected in projecting spinal neurons (Gamboa-Esteves, F. O. *et al.*, 2001b; Tavares, I. and Lima, D., 2002).

5.35.3.2.6 Response properties

The few data regarding the response characteristics of spino-DRt neurons rely on the induction of the c-*fos* proto-oncogene as a marker of activation of spinal neurons following noxious stimulation (Hunt, S. P. *et al.*, 1987). This kind of approach only permitted to conclude on the activation by various kinds of cutaneous and visceral noxious stimulation of DRt-projecting lamina I neurons of all the three structural groups involved, namely multipolar, flattened, and pyramidal (Almeida, A. and Lima, D., 1997). The rate of activation of DRt-projecting

lamina I neurons varied from 20% to 80% depending on the kind of stimulation applied and the neuronal cell group (Almeida, A. and Lima, D., 1997). In the deep dorsal horn, although high levels of c-*fos* expression were observed, the amount of activation of projecting neurons did not exceed 5%. Electrophysiological studies are absolutely needed to further characterize the response properties of spino-DRt neurons and to clarify the involvement of the deep dorsal horn in the transmission of nociceptive input to the DRt.

5.35.3.2.7 Pathways driven at the target

Projections from the DRt reach the parafascicular, ventromedial, and reunions thalamic nuclei (Figure 8) in the rat (Villanueva, L. *et al.*, 1998), which in turn are connected with telencephalic areas involved in emotional/affective and cognitive control. A putative spinoreticulothalamocortical projection relayed at the DRt has been proposed (Desbois, C. and Villanueva, L., 2001). Widespread projections to other brain targets of nociceptive ascending pathways have also been described. These include the VLM; the NTS; the rostral ventromedial medulla; the pontine noradrenergic cell groups A_5, A_6, and A_7 (PBN); the PAG; the posterior thalamus; the hypothalamus; the septal nuclei; the globus pallidus; and the amygdala (Figure 8) (Bernard, J. F. and Besson, J. M., 1990; Bernard, J. F. *et al.*, 1990; Villanueva, L. *et al.*, 1998; Leite-Almeida, H. *et al.*, 2006). Important projections to the orofacial motor nuclei (Bernard, J. F. *et al.*, 1990; Leite-Almeida, H. *et al.*, 2006) as well as to the deep cerebellar nuclei (Leite-Almeida, H. *et al.*, 2006) favor an important role in the organization of facial expressions and vocalization triggered by noxious stimulation.

The DRt also projects to the spinal cord superficial (Tavares, I. and Lima, D., 1994) and deep dorsal horn (Tavares, I. and Lima, D., 1994; Villanueva, L. *et al.*, 1995) as well as to the intermediate/ventral horn (Villanueva, L. *et al.*, 1995). DRt axons terminating in lamina I participate in a closed reciprocal spinodorsal DRt-spinal loop which, based on the asymmetric structure of synapses, is likely to be excitatory at both the spinal and medullary levels (Figure 9) (Almeida, A. *et al.*, 1993; Almeida, A. *et al.*, 2000; Lima, D. and Almeida, A., 2002). Nociceptive input arriving at the DRt is thus thought to drive a reverberating, lamina I centered pain facilitatory circuit, which is in accordance with the high proportion of c-*fos* activated spino-DRt neurons when compared to that of activated cells projecting to other targets (Lima, D., 1998). A ventral DRt-deep dorsal horn pain facilitatory loop is also likely to be established as indicated by the increased responsiveness of WDR deep dorsal horn neurons upon DRt stimulation (Dugast, C. *et al.*, 2003).

5.35.3.3 Nucleus Tractus Solitarii

5.35.3.3.1 Spinal laminae of origin and sites of termination

The spino-NTS pathway was demonstrated in the rat (Menétrey, D. and Basbaum, A. I., 1987; Leah, J. *et al.*, 1988; Esteves, F. *et al.*, 1993) and pigeon (Galhardo, V. *et al.*, 2000). It originates in laminae I, IV–VI, VII, X, and the lateral spinal nucleus, mainly contralaterally, but with an important ipsilateral component (Figure 10) (Esteves, F. *et al.*, 1993).

In the rat, the thoracic and sacral autonomic cell columns were also shown to participate (Menétrey, D. and Basbaum, A. I., 1987; Menétrey, D. and DePommery, J., 1991). In addition, an important contribution from the superficial laminae of the spinal trigeminal nucleus, *pars caudalis*, was revealed (Menétrey, D. and Basbaum, A. I., 1987). The spino-NTS pathway terminates in the caudal part of the NTS, the general visceral zone (Figure 10) (Loewy, A. D., 1990). Based on restricted retrograde tracer injections, cells projecting to the lateral subnucleus are fewer than those targeting the medial NTS, and do not include lamina I cells (Figure 10) (Esteves, F. *et al.*, 1993). Anterograde tracing confirmed this finding by showing that fibers originating in the superficial dorsal horn terminate bilaterally in the medial part of the commissural subnucleus, while fibers originating in the deep dorsal horn terminate ipsilaterally in the lateral subnucleus, with a few fibers distributed to the dorsomedial subnucleus (Gamboa-Esteves, F. O. *et al.*, 2001c).

5.35.3.3.2 Structural types of neurons involved

Again, studies referring to the structural characteristics of spino-NTS neurons only addressed lamina I. Similar to what was observed for the VLM, lamina I neurons projecting to the NTS belong in the fusiform, pyramidal, and flattened groups. However, contrary to the VLM, fusiform neurons contribute a small fraction. In spite of constituting half of the lamina I neuronal population (Lima, D. and Coimbra, A., 1983; Lima, D. and Coimbra, A., 1986), fusiform neurons amount only to 25% of NTS-projecting lamina I neurons, whereas flattened and pyramidal neurons make up

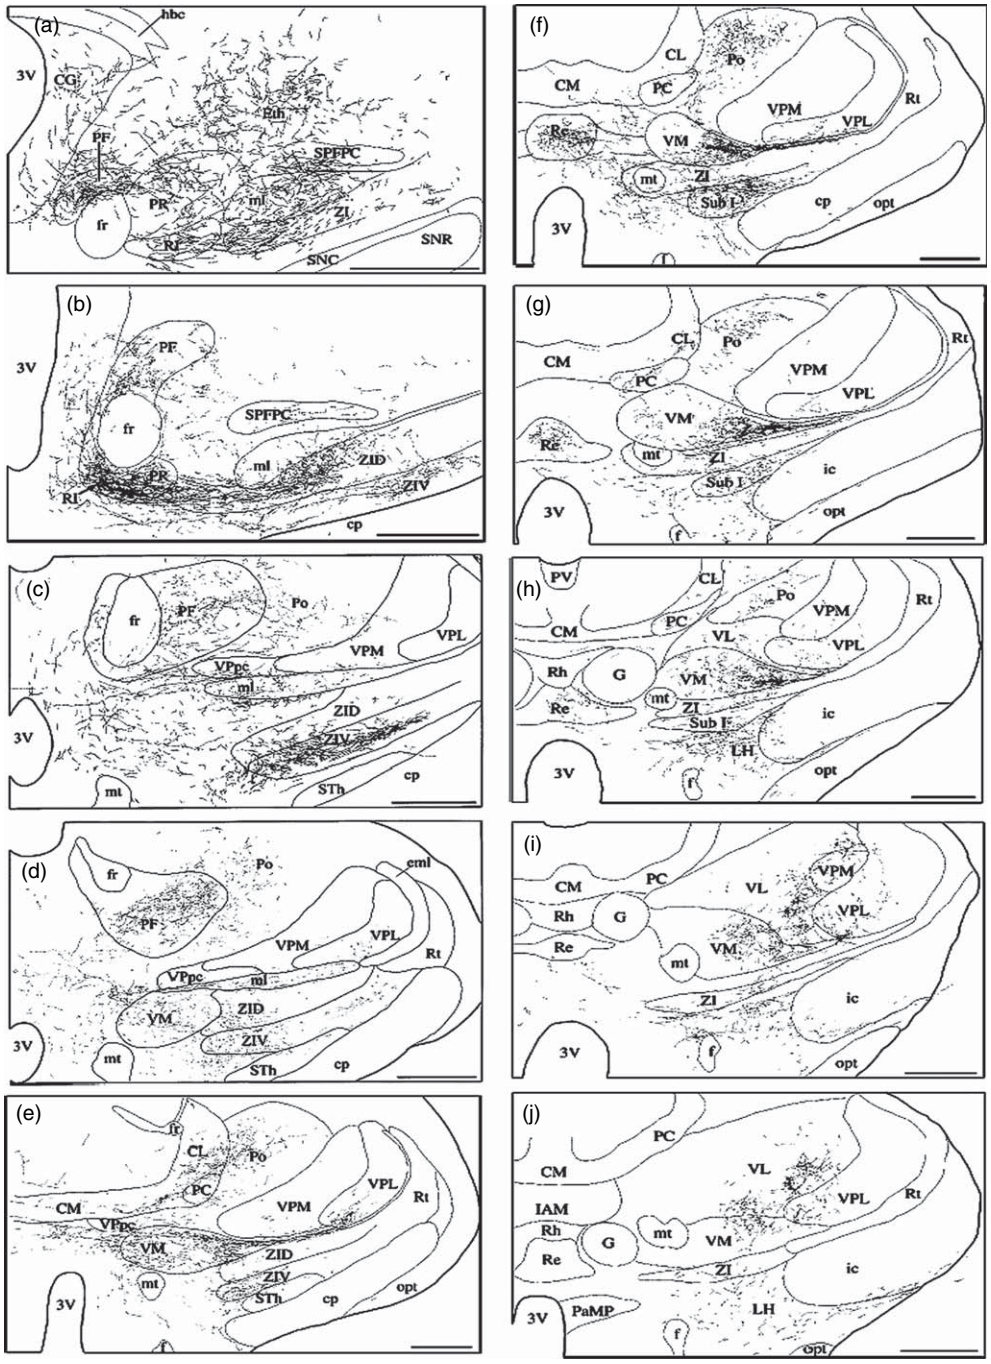

Figure 8 Distribution of DRt efferents anterogradely labeled with *phaseolus vulgaris* leucoagglutinin (PHA-L) in the diencephalon and telencephalon, in horizontal view. Adapted from figure 6 of Villanueva, L., Desbois, C., Le Bars, D., and Bernard, J. F. 1998. Organization of diencephalic projections from the medullary subnucleus reticularis dorsalis and the adjacent cuneate nucleus: a retrograde and anterograde tracer study in the rat. J. Comp. Neurol. 390, 133–160.

about 35–40% each. Similar relative amounts were observed in the pigeon, although pyramidal cells prevailed followed by flattened and fusiform cells (Galhardo, V. *et al.*, 2000). The abundant participation of flattened cells in the spino-NTS pathway deserves particular attention since it may be related to the specific role of this pathway in pain processing. Flattened cells make up 10% of the entire lamina I

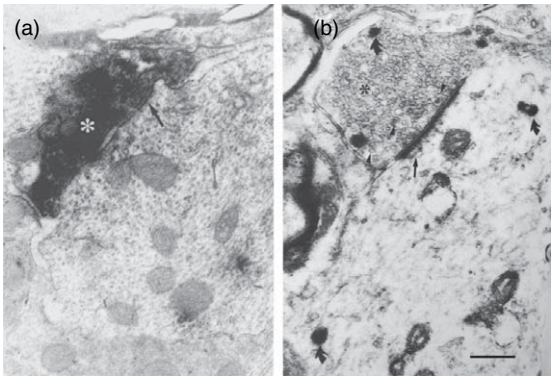

Figure 9 Anterogradely labeled axonal bouton (*) in the DRt (a) and superficial dorsal horn (b) establishing asymmetric synaptic contacts (arrows) upon retrogradely labeled dendrites after injecting cholera toxin subunit B (CTb) in the superficial dorsal horn (a) or horseradish peroxidase (HRP) in the dorsal DRt (b). In (b), tracer deposits are pointed by cuved arrows. Scale bar −0.3 μm (a) Adapted from figure 3 of Almeida, A., Tavares, I., and Lima, D. 2000. Reciprocal connections between the medullary dorsal reticular nucleus and the spinal dorsal horn in the rat. Eur. J. Pain. 4, 373–387. (b) Adapted from figure 3 of Almeida, A., Tavares, I., Lima, D., and Coimbra, A. 1993. Descending projections from the medullary dorsal reticular nucleus make synaptic contacts with spinal cord lamina I cells projecting to that nucleus: an electron microscopic tracer study in the rat. Neuroscience 55, 1093–1106.

neuronal population and participate in a similar proportion in the spino-VLM (Lima, D. *et al.*, 1991) and the spino-DRt (Lima, D. and Coimbra, A., 1990) pathways. Their relative amount in the NTS system is, however, particularly high surpassing the one observed in the lateral spinothalamic system (25–30% at the spinal enlargements).

5.35.3.3.3 Spinal location of ascending fibers

By comparing anterograde tracing produced by injections centered in the dorsal funiculus or the dorsolateral fasciculus with that obtained from superficial or deep dorsal horn laminae, it was concluded that fibers from lamina I neurons course in the dorsal funiculus and fibers from deep dorsal horn neurons in the dorsolateral fasciculus (Figure 10) (Gamboa-Esteves, F. O. *et al.*, 2001c).

5.35.3.3.4 Neurotransmitters

A small fraction of the neurons projecting to the NTS was found, in immunocytochemical studies, to contain dynorphin in lamina I, VIP in the lateral spinal nucleus, and bombesin in lamina X (Leah, J. *et al.*, 1988). Calbindin was immunodetected in spinal NTS-projecting neurons located mainly in lamina I (Figure 11) and the lateral spinal nucleus (Menétrey, D. *et al.*, 1992b; Gamboa-Esteves, F. O. *et al.*, 2001a), as well as in lamina I of the spinal trigeminal nucleus, *pars caudalis* (Menétrey, D. *et al.*, 1992a). In lamina I, about 40% of fusiform NTS-projecting neurons contain calbindin. Pyramidal and flattened neurons also exhibit calbindin (Figure 11), but in smaller fractions (Gamboa-Esteves, F. O. *et al.*, 2001a). Glutamate also occurs mainly in fusiform neurons followed by pyramidal neurons, and co-localizes extensively with calbindin (Gamboa-Esteves, F. O. *et al.*, 2001a). Nitric oxide synthase is present in fewer cells, almost all of them the fusiform type (Gamboa-Esteves, F. O. *et al.*, 2001a). Calbindin-immunoreactive NTS-projecting neurons are c-*fos* activated by visceral and cutaneous stimulation (Gamboa-Esteves, F. O. *et al.*, 2001b). Glutamate-positive and nitric oxide synthase-positive neurons are c-*fos* activated only by visceral stimulation (Gamboa-Esteves, F. O. *et al.*, 2001b). About 5% neurons of NTS-projecting neurons of the pyramidal group are immunoreactive for substance P (Gamboa-Esteves, F. O. *et al.*, 2001a).

5.35.3.3.5 Response properties

By the use of the c-*fos* approach, spino-NTS neurons located in lamina I were shown to be activated by cutaneous and visceral noxious stimulation (Menétrey, D. and DePommery, J., 1991; Lima, D. *et al.*, 1994; Gamboa-Esteves, F. O. *et al.*, 2001b). They belong in the three neuronal groups that participate in the pathway (Esteves, F. *et al.*, 1993) irrespective of the kind of cutaneous or visceral noxious stimulation employed (Lima, D. *et al.*, 1994). However, cells activated by visceral input prevail over those activated by cutaneous input, and neurochemical differences between cutaneous- and visceral-activated cells were found (Gamboa-Esteves, F. O. *et al.*, 2001b).

5.35.3.3.6 Pathways driven at the target

The caudal NTS projects to several brain areas involved in pain processing such as the caudal ventrolateral reticular formation (Cobos, A. *et al.*, 2003), the dorsal reticular nucleus (Almeida, A. *et al.*, 2002), the rostral ventromedial medulla (Sim, L. J. and Joseph, S. A., 1994), the PBN (Cechetto, D. F. *et al.*, 1985), the PAG (Bandler, R. and Tork, I., 1987; Herbert, H. and Saper, C. B., 1992), and the hypothalamus (Reis, L. C. *et al.*, 2000). The NTS is also connected with the medullary vasopressor (Agarwal, S. K. and Calaresu,

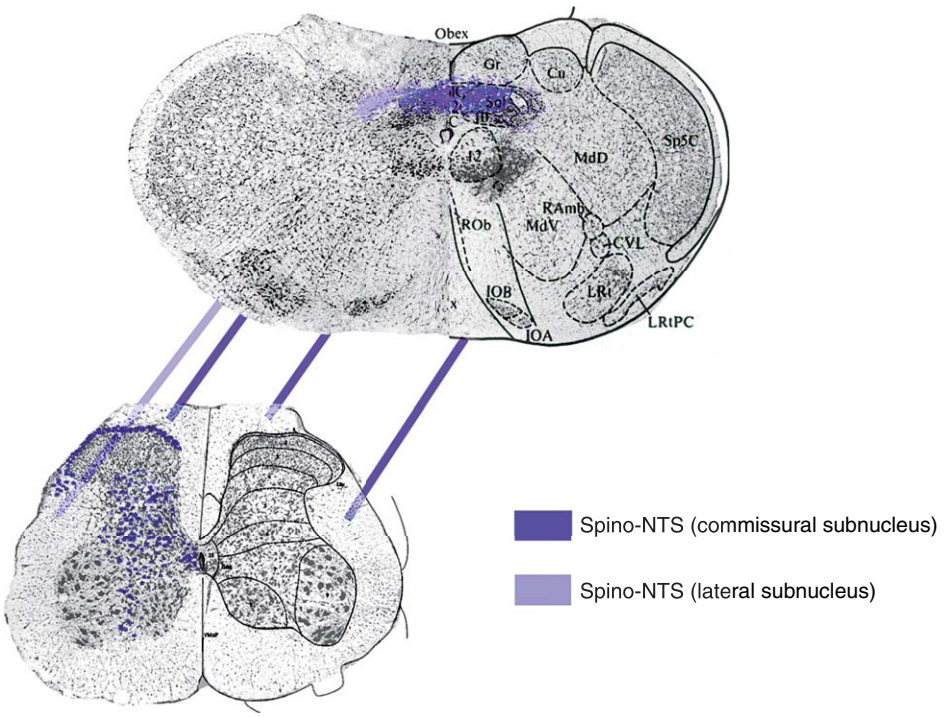

Figure 10 Diagram representing the spinal laminae of origin, ascending course in the spinal cord, and areas of termination of the spino-NTS pathway. Note the deep dorsal horn location of neurons terminating in the lateral subnucleus. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

F. R., 1990) and vasodepressor (VLM) areas (Cobos, A. *et al.*, 2003). Although the NTS–VLM pathway is potentially involved in nociceptive/cardiovascular integration (Tavares, I. *et al.*, 1997), different VLM neurons are likely to mediate the antinociceptive and vasodepressive effects (Lima, D. *et al.*, 2001).

The caudal NTS also gives rise to projections descending directly to the spinal cord (Loewy, A. D. and Burton, H., 1978; Mtui, E. P. *et al.*, 1993; Tavares, I. and Lima, D., 1994). NTS fibers targeting the dorsal horn originate in the commissural subnucleus and terminate in superficial laminae (Tavares, I. and Lima, D., 1994).

5.35.3.4 Rostral Ventromedial Medulla

5.35.3.4.1 Spinal laminae of origin and sites of termination

Spinal cells projecting in the spino-RVM pathway predominate in laminae V, VII, VIII, and X (Figure 12) in the rat (Maunz, R. A. *et al.*, 1978; Kevetter, G. A. and Willis, W. D., 1982; Kevetter, G. A. *et al.*, 1982; Kevetter, G. A. and Willis, W. D., 1983; Chaouch, A. *et al.*, 1983; Peschanski, M. and Besson, J. M., 1984; Nahin, R. L. and Micevych, P. E., 1986; Nahin, R. L. *et al.*, 1986), cat (Abols, I. A. and Basbaum, A. I., 1981; Ammons, W. S., 1987), and monkey (Haber, L. H. *et al.*, 1982; Kevetter, G. A. *et al.*, 1982).

The pathway is mainly contralateral, although a large number of ipsilaterally and bilaterally projecting cells have also been reported (Figure 12) (Haber, L. H. *et al.*, 1982; Thies, R. and Foreman, R. D., 1983; Foreman, R. D. *et al.*, 1984; Ammons, W. S., 1987). Cells are distributed throughout the entire length of the spinal cord, but are much more numerous at the upper cervical level due to an important contribution of the ipsilateral ventral horn (Kevetter, G. A. and Willis, W. D., 1983). Scattered neurons were observed in lamina I (Foreman, R. D. *et al.*, 1984; Leah, J. *et al.*, 1988) and the lateral spinal nucleus in the rat (Leah, J. *et al.*, 1988). The axonal termination domain distributes through the nucleus reticularis gigantocellularis and the nucleus paragigantocellularis (Figure 12) (Bowsher, D. and Westman, J., 1970; Kerr, F. W. L., 1975; Peschanski, M. and Besson, J. M., 1984). In the cat and monkey, fibers originating in lamina I were seen to extend medially through the reticular formation to terminate in nucleus raphe magnus (Craig, A. D., 1995).

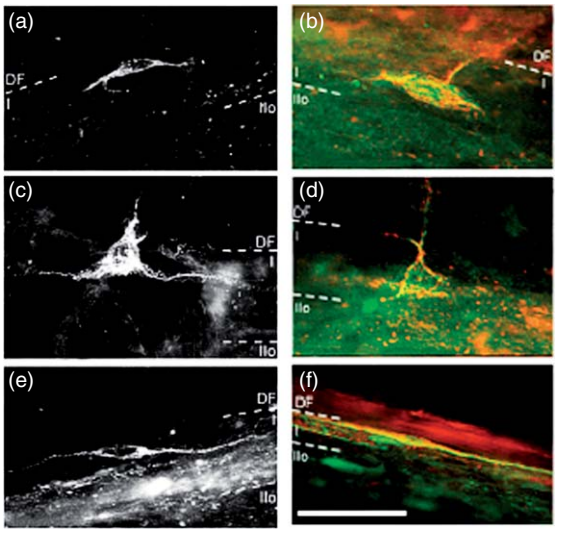

Figure 11 Lamina I neurons of the flattened (a, b), pyramidal (c, d), and fusiform (e, f) types retrogradely labeled with cholera toxin subunit B (CTb) from the NTS, in parasagittal view. In (b, d, and f), retrogradely labeled neurons present immunoreactivity for calbindin (green). Scale bar = 50 μm. (Adapted from figures 3 and 5 of Gamboa-Esteves, F. O., Kaye, J. C., McWilliam, P. N., Lima, D., and Batten, T. F. 2001a. Immunohistochemical profiles of spinal lamina I neurons retrogradely labelled from the nucleus tractus solitarii in rat suggest excitatory projections. Neuroscience 104, 523–538).

5.35.3.4.2 Structural types of neurons involved

Spino-RVM neurons located in lamina VII in the monkey were structurally relatively small as compared to spinothalamic neurons, with multipolar or, less frequently, fusiform or round perikarya and long dendrites across the lateromedial axis (Kevetter, G. A. *et al.*, 1982).

5.35.3.4.3 Spinal location of ascending fibers

Spino-RVM axons course in the contralateral ventrolateral quadrant in the spinal cord (Figure 12) and follow ventrolaterally in the caudal medulla oblongata before they turn medially to reach their sites of termination (Rossi, G. F. and Brodal, A., 1957; Anderson, F. D. and Berry, C. M., 1959; Mehler, W. R. *et al.*, 1960; Kerr, F. W. L., 1975; Nahin, R. L. *et al.*, 1986).

5.35.3.4.4 Neurotransmitters

Immunocytochemical staining for enkephalin was observed in spino-RVM neurons located in laminae VII and X (Nahin, R. L. and Micevych, P. E., 1986). Neurons in lamina X were also shown to contain cholecystokinin (CCK), somatostatin and, in fewer numbers, bombesin (Leah, J. *et al.*, 1988). In the lateral spinal nucleus, a relatively large neuronal population is immunoreactive to VIP, while bombesin and dynorphin are expressed in just a few neurons (Leah, J. *et al.*, 1988). Scarce somatostatin-immunoreactive neurons occur in lamina V (Leah, J. *et al.*, 1988).

5.35.3.4.5 Response properties

Spino-RVM neurons are excited by stimulation of Aδ and C fibers from the skin, muscles, and viscera (Maunz, R. A. *et al.*, 1978; Thies, R. and Foreman, R. D., 1983; Foreman, R. D. *et al.*, 1984; Ammons, W. S., 1987). Both noxious and innocuous stimulation are effective, but the majority of RVM-projecting neurons are nociceptive (Maunz, R. A. *et al.*, 1978; Haber, L. H. *et al.*, 1982; Thies, R. and Foreman, R. D., 1983; Foreman, R. D. *et al.*, 1984). Neurons responding only to cutaneous input belong in the LT, WDR, and NS classes (Fields, H. L. *et al.*, 1977). Receptive fields vary from limited (Fields, H. L., *et al.*, 1977) to large and complex, often including inhibitory regions (Fields, H. L. *et al.*, 1977; Maunz, R. A. *et al.*, 1978; Cervero, F. and Wolstencroft, J. H., 1984). Neurons responding to stimulation of deep structures are particularly numerous. They are mostly activated by deep noxious stimulation (Cervero, F. and Wolstencroft, J. H., 1984) and may receive convergent noxious or innocuous input from the skin (Fields, H. L. *et al.*, 1977; Cervero, F. and Wolstencroft, J. H., 1984). Neurons responsive to cutaneous, deep, and visceral noxious stimulation have also been reported (Foreman, R. D. *et al.*, 1984; Blair, R. W. *et al.*, 1984a, 1984b; Ammons, W. S., 1987). The majority of these cells belong in the high-threshold class, the remaining being WDR neurons (Thies, R. and Foreman, R. D., 1983; Foreman, R. D. *et al.*, 1984). Similar to pure somatic neurons, spinoreticular neurons with visceral input present either well-delimited or complex receptive fields, the latter including areas resulting in innocuous- or noxious-evoked inhibition (Thies, R. and Foreman, R. D., 1983; Foreman, R. D. *et al.*, 1984). Ten percent to 20% of the neurons projecting to the RVM also target the lateral thalamus (Haber, L. H. *et al.*, 1982; Foreman, R. D. *et al.*, 1984).

5.35.3.4.6 Pathways driven at the target

The RVM was shown to project to the medial thalamus, including the intralaminar complex (Giesler, G.

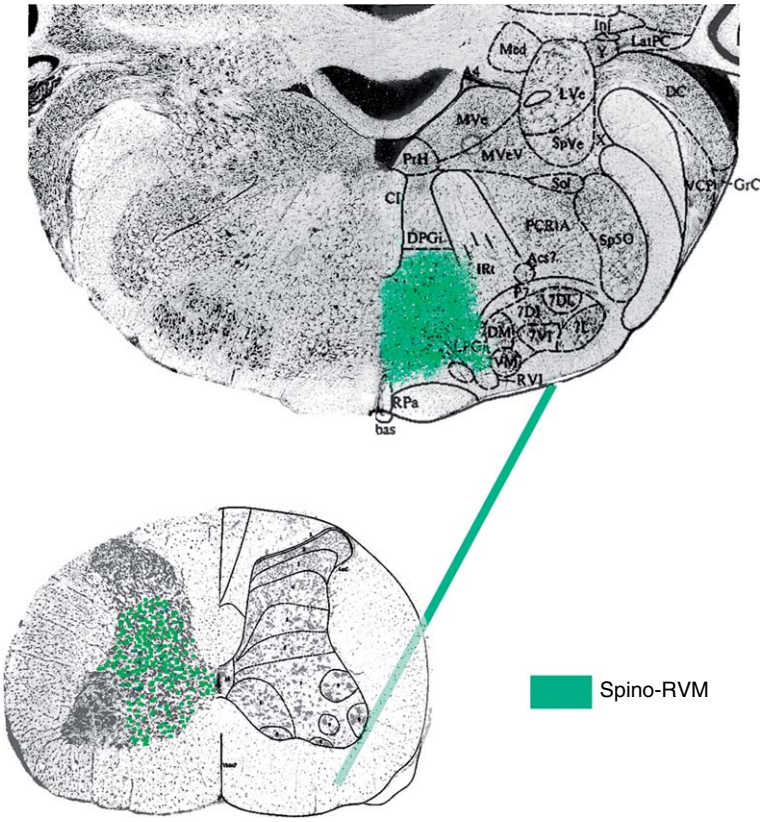

Figure 12 Diagram representing the spinal laminae of origin, ascending course in the spinal cord, and areas of termination of the spino-RVM pathway. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

J. *et al*., 1981b; Peschanski, M. and Besson, J. M., 1984), and hence was proposed to function as a relay station in a spinoreticulothalamic pathway involved in motor responses to noxious stimulation. It is also at the origin of an important pain control descending pathway that terminates in the superficial and deep dorsal horn and includes pain inhibitory and facilitatory neurons (Fields, H. L. *et al*., 1995; Fields, H. L., 2000).

5.35.4 Spinopontine Pathways

The search for spinal fibers terminating in the brainstem (Craig, A. D., 1995), in particular in catecholaminergic nuclei (Westlund, K. N. and Craig, A. D., 1996), revealed various pontine spinal targets, which include the ventrolateral pons (A5), the locus coeruleus (A6), the subcoerulear region, the Kölliker–Fuse nucleus, and the PBN (Figure 13). These studies were, however, focused on lamina I ascending fibers, and, except for the PBN, such putative nociceptive pathways were not thoroughly investigated. This section will, therefore, deal only with the spino-PBN system.

5.35.4.1 Parabrachial Nuclei

5.35.4.1.1 Spinal laminae of origin and sites of termination

Injections centered in the PBN in both the rat (Cechetto, D. F. *et al*., 1985; Lima, D. and Coimbra, A., 1989; Hylden, J. L. *et al*., 1989; Menétrey, D. and DePommery, J., 1991; Traub, R. J. and Murphy, A., 2002) and cat (Panneton, W. M. and Burton, H., 1985; Hylden, J. L. K. *et al*., 1986a; 1986b) produce dense bilateral retrograde labeling in lamina I, mainly near the dorsal root entry zone, as well as in the lateral reticular portion of lamina V and laminae VIII and X (Figure 13). Additional labeling was observed in the intermediolateral column at thoracic levels, and in the parasympathetic column at sacral levels (Menétrey, D. and DePommery, J. 1991). Spino-PBN neurons with

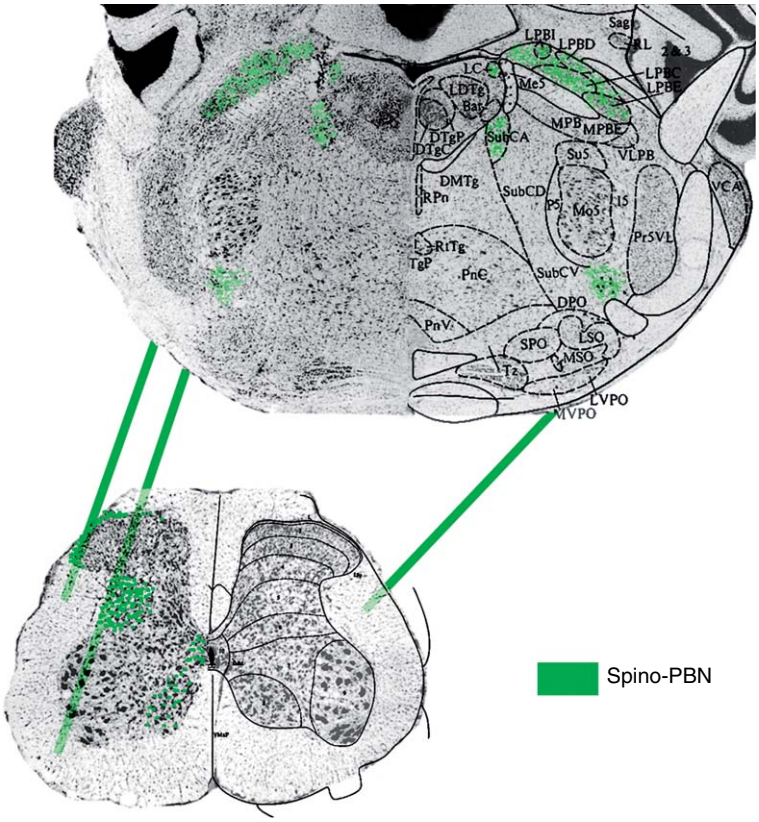

Figure 13 Diagram representing the spinal laminae of origin, ascending course in the spinal cord, and areas of termination of the spino-PBN pathway. Note the preferential lateral location of dorsal horn neurons. Spinal axonal termination areas in the locus coeruleus (LC), nucleus subcoeruleus (subCA) and the A_5 noradrenergic group are also represented. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

axonal collaterals to the lateral thalamus were observed in all spinal areas with a marked prevalence in lamina I (Hylden, J. L. K. *et al.*, 1985; Hylden, J. L. *et al.*, 1989). A large percentage of spino-PBN neurons also project to the VLM (Spike, R. C. *et al.*, 2003).

The areas of termination of spinal fibers in the PBN are distributed bilaterally through the dorsal part of the lateral parabrachial nucleus, namely the dorsal, central, internal, and superior lateral subnuclei and the Kölliker–Fuse (Figure 13) (Cechetto, D. F. *et al.*, 1985; Blomqvist, A. *et al.*, 1989; Slugg, R. M. and Light, A. R., 1994). The medial and ventral lateral subnuclei are not targeted by spinal axons (Cechetto, D. F. *et al.*, 1985). No topographical arrangement has been disclosed (Blomqvist, A. *et al.*, 1989).

5.35.4.1.2 Structural types of neurons involved

Lamina I neurons labeled retrogradely in the rat following CTb injections centered in the PBN (although extending to the cuneiform nucleus) belonged in the fusiform (65–70%) and pyramidal (30–35%) groups (Lima, D. and Coimbra, A., 1989). In the cat, lamina I neurons antidromically activated from mesencephalic sites with similar location and intracellularly stained resembled fusiform neurons (Figure 14) both from the description of their longitudinally extended spiny dendritic arbors and from their camera lucida drawings (Hylden, J. L. K. *et al.*, 1986a; see Figure 5).

5.35.4.1.3 Spinal location of ascending fibers

In the cat, spino-PBN fibers course bilaterally in the dorsolateral fasciculus and ipsilaterally in the ventrolateral and ventral funiculi (Figure 13) (Hylden, J. L. K. *et al.*, 1986b; Hylden, J. L. *et al.*. 1989). Fibers originated in lamina I were shown to ascend through the dorsal aspect of the dorsolateral fasciculus (Hylden, J. L. K. *et al.*, 1986b). About one-fifth of

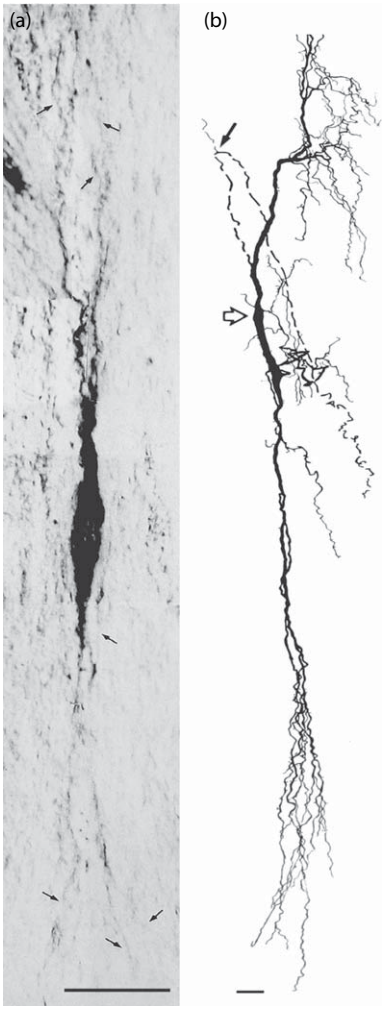

Figure 14 Lamina I PBN-projecting neurons retrogradely labeled with CTb (a) or intracellularly stained during antidromic activation (b), in horizontal (a) and parasagittal (b) views. In (a), arrows point to thin distal dendritic branches. In (b), the arrow points to the axon and the open arrow to the cell body. Scale bars = 30 μm. (a) Adapted from figure 4 of Lima, D. and Coimbra, A. 1989. Morphological types of spinomesencephalic neurons in the marginal zone (lamina I) of the rat spinal cord, as shown after retrograde labeling with cholera toxin subunit B. J. Comp. Neurol. 279, 327–339. (b) Adapted from figure 5 of Hylden, J. L. K., Hayashi, H., Dubner, R., and Bennett, G. J. 1986a. Physiology and morphology of the lamina I spinomesencephalic projections. J. Comp. Neurol. 247, 505–515).

lamina I neurons project bilaterally along the spinal cord (Hylden, J. L. K. *et al.*, 1986a).

5.35.4.1.4 Surface receptors

Most spino-PBN neurons located in lamina I express the NK1 receptor (Todd, A. J. *et al.*, 2000; Spike, R. C. *et al.*, 2003), and most lamina I neurons expressing the NK1 receptor and receiving synaptic contacts from TRPV1 immunoreactive primary afferent fibers project to the PBN (Hwang, S. J. *et al.*, 2003). Lamina I PBN-projecting Giant cells (lamina I cells three times larger than the remaining, amounting to about 5% in each lamina I structural group) (Lima, D. and Coimbra, A., 1983, 1986) of the pyramidal type were shown to lack the NK1 receptor and exhibit instead the glycine receptor-associated protein gephyrin (Puskar, Z. *et al.*, 2001). These cells are apposed by nitric oxide synthase and GABA-containing axonal boutons (Puskar, Z. *et al.*, 2001). In the deep dorsal horn, about 60% of NK1-immunoreacive neurons project to the PBN (Todd, A. J. *et al.*, 2000).

5.35.4.1.5 Neurotransmitters

Around half of the lamina I neuronal population projecting to the PBN immunostains for either dynorphin or enkephalin. Staining of sequential sections did not reveal co-localization of the two peptides (Standaert, D. *et al.*, 1986). According to Lima and colleagues (Lima, D. and Coimbra, A., 1989; Lima, D. *et al.*, 1993), lamina I enkephalinergic PBN-projecting cells should belong in the pyramidal group, whereas dynorphinergic cells could be either pyramidal or fusiform. Lumbosacral neurons projecting both ipsi- and contralaterally, mainly from lamina I and the lateral spinal nucleus, are immunoreactive for calbindin (Menétrey, D. *et al.*, 1992b).

5.35.4.1.6 Response properties

Neurons antidomically activated from the PBN in lamina I of the lumbar spinal cord of the rat (Bester, H. *et al.*, 2000) and cat (Hylden, J. L. K. *et al.*, 1985; Hylden, J. L. K. *et al.*, 1986a) belong mostly in the NS class (75–90%), the remaining being WDR neurons. They present extremely low spontaneous activity and small receptive fields, respond to stimulation of Aδ and C primary afferent fibers and conduct in the C–Aδ range (Hylden, J. L. K. *et al.*, 1986a; Bester, H. *et al.*, 2000). The large majority respond to both mechanical and heat-noxious stimulation and a few also to noxious cold stimulation. C-*fos* studies identified thoracolumbar spino-PBN neurons located preferentially in the superficial dorsal horn that were activated by visceral input (Menétrey, D. and DePommery, J., 1991; Traub, R. J. and Murphy, A., 2002). In whole-cell patch-clamp recordings, most lamina I neurons projecting to the PBN present a gap firing pattern, with a voltage-dependent delay in action potential firing, which was only shared by part

of the neurons projecting to the PAG and not by neurons that were not labeled from these two sites (Ruscheweyh, R. *et al.*, 2004).

5.35.4.1.7 Pathways driven at the target

By combining antidromic activation from the thalamus with orthodromic activation from the periphery, Bourgeais and coworkers (Bourgeais, L. *et al.*, 2001b) demonstrated that neurons in the parabrachial internal lateral nucleus responding exclusively, with sustained firing, to noxious stimulation of large receptive fields, project to the paracentral thalamic nucleus. This spino-PBN-paracentral thalamic pathway was claimed to be responsible for triggering the aversive reactions to pain at the prefrontal cortex. By the use of a similar approach as well as by anatomical tracing, a spino-PBN-amygdaloid pathway with relay neurons in the external pontine parabrachial area and terminating in the lateral capsular division of the central nucleus of the amygdala was demonstrated (Ma, W. and Peschanski, M., 1988; Bernard, J. F. and Besson, J. M., 1990). This pathway was confirmed by retrograde transneuronal tracing from the amygdala with pseudorabies virus, and found to originate mainly in lamina I neurons (Jasmin, L. *et al.*, 1997).

5.35.5 Spinomesencephalic Pathways

Spinomesencephalic pathways target a multitude of regions located close to each other, which include the PAG, the intercollicular nucleus, the superior colliculus, the cuneiform nuclei, the posterior and anterior pretectal nuclei, and the nucleus of Darkschewitsch (Wiberg, M. and Blomqvist, A., 1984; Björkeland, M. and Boivie, J., 1984; Yezierski, R. P., 1988). The PAG itself, the major target of spinofugal mesencephalic pathways, has its spinal afferents distributed through several areas, each one playing particular integrative roles (Yezierski, R. P., 1988). Most retrograde tracing studies that refer to the spino-PAG pathway are based on injections that encompass different areas of the PAG as well as part of the above referred neighbor regions. Since the PAG is the principal site of termination of the spinomesencephalic tract, this chapter, will focus on the spino-PAG pathway without separating the various mesencephalic targets, as a large number of studies addressing this ascending system do. However, it should be kept in mind that it comprises several parallel systems that are likely to deal with different aspects of pain processing.

5.35.5.1 Periaqueductal Gray

5.35.5.1.1 Spinal laminae of origin and sites of termination

Neurons of origin of the spino-PAG pathway are located in lamina I, the reticular region of laminae IV–V, laminae VI–VIII, lamina X, and the lateral spinal nucleus (Figure 15) in the rat (Menétrey, D. *et al.*, 1982; Beitz, A. J., 1982; Liu, R. P., 1983; Swett, J. E. *et al.*, 1985; Yezierski, R. P., 1988; Lima, D. and Coimbra, A., 1989; Yezierski, R. P. and Broton, J. G., 1991; Yezierski, R. P. and Mendez, C. M., 1991), cat (Wiberg, M. and Blomqvist, A., 1984; Yezierski, R. P., 1988), and monkey (Trevino, D. L., 1976; Mantyh, P. W., 1982; Wiberg, M. *et al.*, 1987; Yezierski, R. P., 1988; Zhang, D. *et al.*, 1990). In the cat, cells located in lamina I were found to account for the majority of spino-PAG neurons in the cervical and lumbar enlargements, but only to around 30% in the remaining spinal segments (Mouton, L. J. *et al.*, 2001). In the rat, an additional important projection, apparently exclusive of this pathway, originates from neurons located inside the white matter overlying lamina I, at the dorsal funiculus (Lima, D. and Coimbra, A., 1989).

Projections originated in the dorsal horn are mainly contralateral, especially from lamina I, the lateral spinal nucleus, and the dorsal funiculus (Trevino, D. L., 1976; Wiberg, M. *et al.*, 1987; Lima, D. and Coimbra, A., 1989), although a significant ipsilateral projection from lumbosacral spinal segments has been reported (Menétrey, D. *et al.*, 1992b). Projections originated in lamina X and the ventral horn are bilateral (Figure 15) (Trevino, D. L., 1976; Wiberg, M. *et al.*, 1987; Lima, D. and Coimbra, A., 1989). The upper cervical cord makes a major additional bilateral contribution both from the ventral horn and the lateral cervical nucleus (Yezierski, R. P. and Mendez, C. M., 1991; Mouton, L. J. and Holstege, G., 2000). Spino-PAG neurons were shown to leave axonal collaterals in the DRt, RVM, and locus coeruleus in the rat (McMahon, S. B. and Wall, P. D., 1985; Pechura, C. and Liu, R., 1986), and to collateralize a lot within the mesencephalon (Hylden, J. L. K. *et al.*, 1985; Yezierski, R. P. and Schwartz, R. H., 1986). Projections to both the mesencephalon and thalamus were reported in the rat (Harmann, P. A. *et al.*, 1988; Yezierski, R. P. and Mendez, C. M., 1991), cat (Hylden, J. L. K. *et al.*, 1986a; Yezierski, R. P. and Broton, J. G., 1991) and

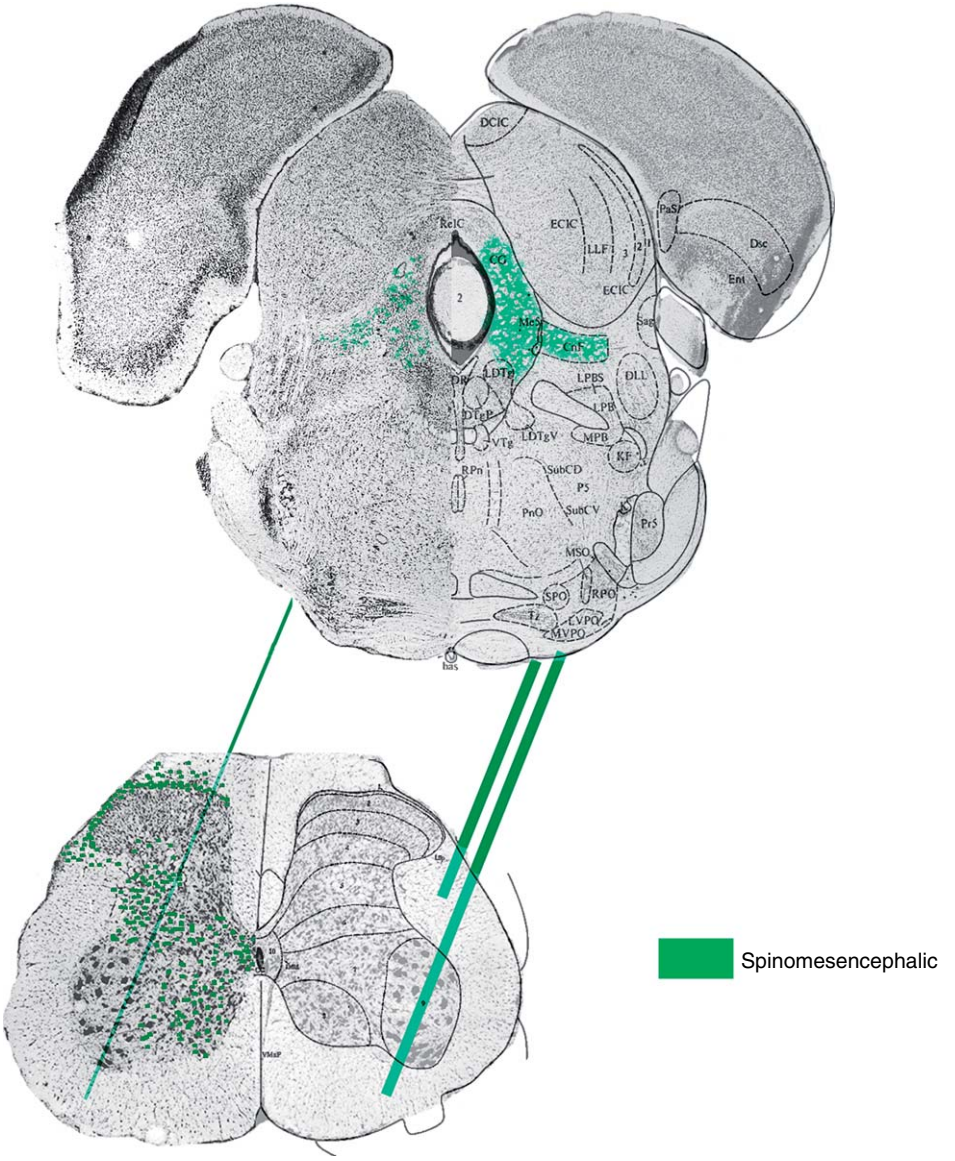

Figure 15 Diagram representing the spinal laminae of origin, ascending course in the spinal cord, and areas of termination of the spinomesencephalc pathway. (Only the caudal termination area is represented) Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

monkey (Price, D. D. *et al*., 1978; Yezierski, R. P. *et al*., 1987; Zhang, D. *et al*., 1990). Thalamic sites of termination are mainly located in the ventrobasal complex, but collateralization to the posterior complex and medial thalamic nuclei has also been observed (Yezierski, R. P. and Mendez, C. M., 1991).

The mesencephalic sites of termination of the fibers ascending from the spinal cord and the spinal trigeminal nucleus were depicted in the rat (Yezierski, R. P., 1988), cat (Wiberg, M. and Blomqvist, A., 1984; Björkeland, M. and Boivie, J., 1984; Wiberg, M. *et al*., 1987; Yezierski, R. P., 1988), and monkey (Kerr, F. W. L., 1975; Wiberg, M. *et al*., 1987; Yezierski, R. P., 1988). The termination pattern is very similar in the three species (Figure 15). With the exception of the nucleus of Darkschewitsch, terminal arborizations are sparse in the most rostral part of the mesencephalon (Yezierski, R. P., 1988; Lima, D. and Coimbra, A., 1989). Fibers are mainly distributed through the middle and caudal part of the PAG, nucleus cuneiformis,

deep and intermediate gray layers of the superior colliculus, and intercollicular nucleus (Wiberg, M. *et al*., 1987; Yezierski, R. P., 1988). In the caudal-most PAG of the monkey, but not in the rat and cat (Figure 16), spinal afferents contribute to two distinct dorsolateral and ventrolateral dense arborizations, while immediately rostrally, in the intercollicular region, they concentrate in a sole domain located laterally (Wiberg, M. *et al*., 1987; Yezierski, R. P., 1988), with additional labeling dorsally to the aqueduct (Yezierski, R. P., 1988).

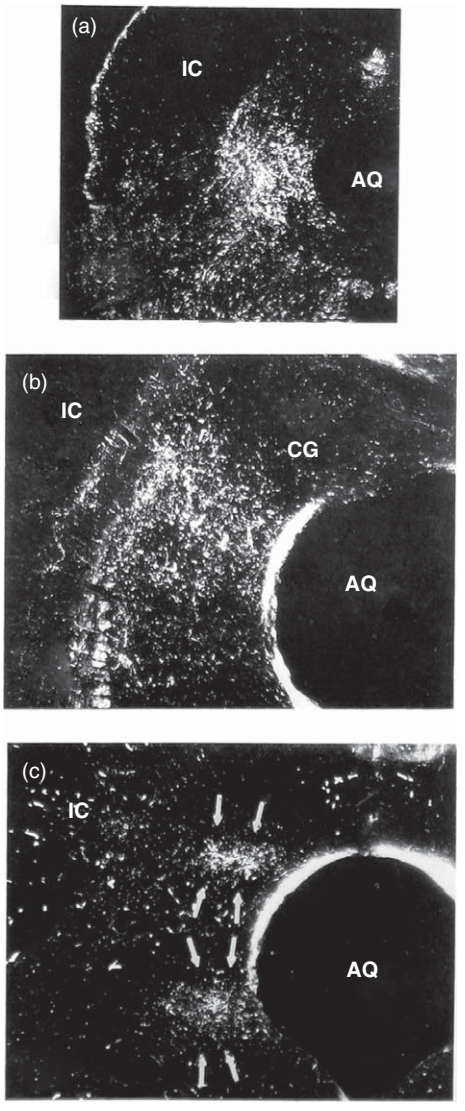

Figure 16 Anterograde labeling in the caudal midbrain following injection of wheat grem agglutinin–horseradish peroxidase (WGA-HRP) in the lumbosacral spinal cord of the rat (a), cat (b), and monkey (c). AQ, Cerebral aqueduct; CG , Periaqueductal gray; IC, Inferior colliculus. Adapted from figure 3 of Yezierski, R. P. 1988. Spinomesencephalic tract: projections from the lumbosacral spinal cord of the rat, cat, and monkey. J. Comp. Neurol. 267, 131–146.

This is an interesting finding in the light of data showing that the dorsolateral/lateral PAG is involved in aversive/defense behavior and vasopressor responses, and the vantrolateral PAG in immobility, positive reinforcing, and vasodepression (Lovick, T. A., 1993).

The possibility that the spino-PAG pathway is a composite of multiple pathways subserving the various functions in which the PAG is involved is supported by studies showing that different regions in the PAG receive afferents from distinct spinal neuronal populations (Keay, K. A. and Bandler, R., 1992; VanderHorst, V. G. J. M. *et al*., 1996; Mouton, L. J. and Holstege, G.., 2000). Neurons at spinal segments C1–C3 that project to the lateral part of the PAG are mainly located in lamina I, whereas those projecting to the ventrolateral part of the PAG prevail in laminae VII–VIII (Keay, K. A. and Bandler, R., 1992). In the lumbosacral spinal cord, neurons in medial lamina VII and lamina VIII terminate in the lateral part of the lateral PAG and adjacent tegmentum, whereas neurons distributed thoughout laminae I and V terminate diffusely in the dorsal and lateral PAG (VanderHorst, V. G. J. M. *et al*., 1996). In the cat, Mouton and Holstege (Mouton, L. J. and Holstege, G., 2000) described five distinct spinal neuronal groups based on their clustering pattern in the spinal cord and termination pattern in the PAG: (1) neurons located in laminae I and V along the entire length of the spinal cord and terminating in all parts of the intermediate and caudal PAG; (2) neurons located bilaterally in lateral laminae VI–VII and dorsolateral lamina VIII of segments C1–C3 and terminating in the ventrolateral and lateral part of the entire PAG and deep tectum; (3) neurons located in lamina X of the thoracic and upper lumbar cord and terminating in the ventrolateral and lateral PAG and deep tectum; (4) neurons located in medial laminae VI–VII of segments L5–S3 and terminating in the lateral and ventrolateral intermediate and caudal PAG; and (5) neurons located laterally in lamina I of segments L6–S2 and laminae V–VII and X of segments S1–S3 and terminating in the medial part of the ventrolateral intermediate and caudal PAG. According to electrophysiologcal studies using antidromic activation (Yezierski, R. P. and Schwartz, R. H., 1986), spinal cells projecting to the rostral-most part of the PAG are located more ventrally, in laminae V–VII, than those projecting to the intercollicular and caudal levels, to where lamina I neurons project.

5.35.5.1.2 Structural types of neurons involved

Spinomesencephalic neurons were characterized as to the size and shape of the soma both in the rat and cat (Menétrey, D. *et al.*, 1980; VanderHorst, V. G. J. M. *et al.*, 1996). Neurons in lamina I are smaller than in other laminae and present oval to fusiform soma in transverse view (VanderHorst, V. G. J. M. *et al.*, 1996). Neurons in the lateral spinal nucleus and lamina X present oval to fusiform soma of variable sizes. Deep dorsal horn and ventral horn neurons are large and multipolar (Menétrey, D. *et al.*, 1980; VanderHorst, V. G. J. M. *et al.*, 1996).

A detailed structural characterization was obtained for lamina I neurons retrogradely labeled with CTb in the rat (Lima, D. and Coimbra, A., 1989). Large numbers of fusiform and pyramidal neurons were shown to participate. However, all injections were directed to the ventrolateral caudal PAG and encompassed part of the PBN. Injections hitting mainly the PBN failed to stain as many pyramidal neurons as those targeting the ventrolateral PAG, while still labeling a relatively large number of fusiform neurons. Pyramidal neurons were therefore taken as projecting mainly to the ventrolateral PAG and fusiform neurons to the PBN (Lima, D. and Coimbra, A., 1989). Some fusiform neurons projecting to the PAG were shown to have myelinated axons and give off collaterals inside lamina I (Hylden, J. L. K. *et al.*, 1986a).

5.35.5.1.3 Spinal location of ascending fibers

Fibers of the spinomesencephalic pathway are classically considered to travel in the ventrolateral quadrant of the spinal white matter (Mehler, W. R. *et al.*, 1960; Kerr, F. W. L., 1975). More recent data using antidromic activation revealed that fibers arising from lamina I decussate near their level of origin and course in the dorsal part of the dorsolateral fasciculus (McMahon, S. B. and Wall, P. D., 1985; Hylden, J. L. K. *et al.*, 1986b).

5.35.5.1.4 Surface receptors

The majority of spino-PAG neurons in lamina I, but not in the deep dorsal horn, express the NK1 receptor (Todd, A. J. *et al.*, 2000). Their amounts are, however, smaller than those of neurons projecting to the VLM or the PBN (Spike, R. C. *et al.*, 2003).

5.35.5.1.5 Neurotransmitters

In the lateral spinal nucleus and lamina X, neurons containing various neuropeptides and projecting to a mesencephalic area centered in the PAG (but extending to the parabrachial nuclei) were observed (Leah, J. *et al.*, 1988). Neurons in the lateral spinal nucleus were immunoreactive for VIP, bombesin, and substance P, while those located in lamina X were immunoreactive for bombesin and enkephalin. A few VIP-immunoreactive neurons were located in lamina I. At lumbosacral spinal levels, calbindin immunoreactive PAG-projecting neurons were observed bilaterally in all spinal areas of origin of the pathway, with a particularly high concentration in lamina I and the lateral spinal nucleus (Menétrey, D. *et al.*, 1992b).

5.35.5.1.6 Response properties

The response properties of spinal neurons projecting to the PAG were recorded in the rat (Menétrey, D. *et al.*, 1980), cat (Yezierski, R. P. and Schwartz, R. H., 1986; Yezierski, R. P. and Broton, J. G., 1991), and monkey (Yezierski, R. P. *et al.*, 1987). PAG-projecting neurons belong in the LT, WDR, and NS classes. Both WDR and NS neurons respond to mechanical and heat stimuli at the noxious range. WDR neurons largely prevail over the other neuronal classes, representing about half of the population recorded. Many WDR cells were found to respond to both cutaneous and visceral/deep tissue stimulation (Yezierski, R. P. and Schwartz, R. H., 1986; Yezierski, R. P. *et al.*, 1987). In the rat, NS neurons are predominant in lamina I, WDR neurons are distributed through both lamina I and the deep dorsal horn, and LT cells prevail in the deep dorsal horn (Menétrey, D. *et al.*, 1980). In the cat and monkey, neurons are distributed evenly through the dorsal horn and around the central canal irrespective of the physiological class they belong to (Yezierski, R. P. and Schwartz, R. H., 1986; Yezierski, R. P. *et al.*, 1987).

C-*fos* studies (Clement, C. I. *et al.*, 2000; Keay, K. A. *et al.*, 2002) revealed neurons at the thoracic spinal cord that project to the rostral ventrolateral PAG to be activated by noxious visceral stimulation. Neurons at both the lumbosacral and upper cervical spinal cord and projecting to the caudal ventrolateral PAG were activated by hind limb muscle noxious stimulation. Lamina I neurons projecting to the caudal ventrolateral PAG at the lumbar enlargement and expressing c-*fos* following either mechanical, thermal, or chemical noxious stimulation of the skin or noxious stimulation of the urinary bladder belong in

both the fusiform and pyramidal groups (Lima, D. *et al*., 1992; Lima, D., 1998).

Most spino-PAG neurons, including those few cells projecting to both the PAG and the ventrobasal complex of the thalamus, present small excitatory receptive fields confined to a single limb (Yezierski, R. P. *et al*., 1987). However, neurons with extensive and complex receptive fields have also been observed, in particular in the upper cervical cord and in deep spinal laminae, including lamina X (Menétrey, D. *et al*., 1980; Yezierski, R. P. and Schwartz, R. H., 1986; Yezierski, R. P., 1990; Yezierski, R. P. and Broton, J. G., 1991). Both groups present complex inhibitory receptive fields and include NS and WDR neurons (Yezierski, R. P. and Schwartz, R. H., 1986; Yezierski, R. P. *et al*., 1987; Yezierski, R. P. and Broton, J. G., 1991).

Spino-PAG lamina I neurons have slow conducting velocities, at the Aδ range, while those in the deep dorsal horn and ventral horn conduct at the low A$_\beta$ range (Yezierski, R. P. *et al*., 1987). Neurons in the lateral spinal nucleus present particularly slow axons, which belong in the unmyelinated and thin myelinated classes (Menétrey, D. *et al*., 1980). A recent study using whole-cell patch-clamp in spinal slices showed that spino-PAG neurons present either gap-firing or burst-firing patterns, contrary to neurons that were not labeled from either the PAG or the PBN (Ruscheweyh, R. *et al*., 2004).

5.35.5.1.7 Pathways driven at the target

The spinomesencephalic pathway was first uncovered as a relay station of the medial spinothalamic tract. Early anatomical studies revealed a projection from the mesencephalon to the intralaminar nuclei of the thalamus (Bowsher, D., 1957). Later anterograde tracing studies confirmed this connection as well as important projections to the hypothalamus, striatum, and amygdala (Eberhart, J. A. *et al*., 1985; Meller, S. T. and Dennis, B. J., 1991). Discrete injections confined to different portions of the PAG in the rabbit showed that the ventral portion is the main source of afferent systems (Meller, S. T. and Dennis, B. J., 1991). Two distinct ascending systems were recognized: a periventricular system terminating in intralaminar and midline thalamic nuclei and along the hypothalamus, and a ventrolateral system terminating in the ventral tegmental area, ventral thalamus, zona incerta, amygdala, substantia innonimata, lateral preopric nucleus, diagonal band of Broca, and the lateral septal nucleus. This multitude of pathways is likely to reflect the morphofunctional complexity of the PAG and is taken as indicative of a PAG role in motor responses, escape/avoidance, aversive versus positive reinforcing, and neuroendocrine and autonomic responses to pain (Lovick, T. A., 1993).

A dense descending projection connects the ventrolateral portion of the caudal PAG with the ipsilateral nucleus raphe magnus (NRM) and adjacent reticular formation, locus coeruleus (LC), nucleus subcoeruleus, and the ventral reticular formation of the medulla (Meller, S. T. and Dennis, B. J., 1991). Sparse fibers originated in the dorsal PAG and superior colliculus also terminate in the locus coeruleus/subcoeruleus area (Cowie, R. J. and Holstege, G., 1992). Since PAG projections to the spinal cord are limited and restricted to laminae VII–VIII (Behbehani, M. M., 1995), the analgesic effects elicited from PAG stimulation are likely to be mediated by these PAG-pontine and PAG-medullary pathways (Lovick, T. A., 1993).

5.35.6 Spinodiencephalic Pathways

Of the pathways terminating in the diencephalon, the spinothalamic are by far those known for longer and therefore more thoroughly investigated. Although a large proportion of the studies dealing with the spinothalamic system address together the lateral and medial pathways, it turned clear from clinical (Dejerine, J. and Roussy, G., 1906; Walker, A. E., 1942a; Hécaen, H. *et al*., 1949), electrophysiological (Kenshalo, D. R., Jr. *et al*., 1979; Giesler, G. J. *et al*., 1981b), and anatomical (Boivie, J., 1979) studies that each pathway is engaged in particular aspects of nociceptive processing. The medial pathway has been implicated in arousal, motivational, affective, and motor responses to pain, and the lateral pathway in stimulus discrimination. Accordingly, in this chapter, the two pathways will be dealt with separately in spite of the difficulties raised by being often assessed as a whole, particularly in retrograde tracing studies. There are, nonetheless, common aspects that will be more thoroughly described in the context of the lateral spinothalamic pathway. Also, a relatively large percentage of spinothalamic neurons (around 15%) of various species and different spinal laminae projects to both the lateral and medial thalamus (Giesler, G. J. *et al*., 1981b; Kevetter, G. A. and Willis, W. D., 1983; Stevens, R. T. *et al*., 1989; Craig, A. D. *et al*., 1989). These neurons share, however, all the properties of lateral spinothalamic neurons

(Giesler, G. J. *et al*., 1981b) and are therefore considered as part of the lateral spinothalamic pathway.

5.35.6.1 Lateral Thalamus

The lateral spinothalamic pathway was the first nociceptive spinofugal pathway described (Edinger, L., 1890). Its identification, at the turning of the nineteenth century, was based on the observation in necropsia tissue from humans, of degenerating profiles at the lateral sensory thalamus after ventrolateral cordotomy that disrupted pain sensation (Quensel, F., 1898; Kohnstamm, O., 1900; Thiele, F. H. and Horsley, V., 1901; Collier, J. and Buzzard, E. F., 1903; Foerster, O. and Gagel, O., 1932; Clark, W. E. L., 1936). Only much later, with the advent of neurophysiology and tracing techniques, this pathway was revealed in detail. Nevertheless, early clinical studies (Dejerine, J. and Roussy, G., 1906; Melzack, R. and Casey, K. L., 1968) correlated the lateral spinothalamic pathway with the discriminative processing of nociceptive input.

5.35.6.1.1 Spinal laminae of origin and sites of termination

The lateral spinothalamic pathway takes origin on the contralateral spinal cord in laminae I, IV–VI, VII–VIII, X, and the lateral spinal nucleus (Figure 17) in the rat, cat, and monkey (Trevino, D. L. and Carstens, E., 1975; Carstens, E. and Trevino, D. L.,

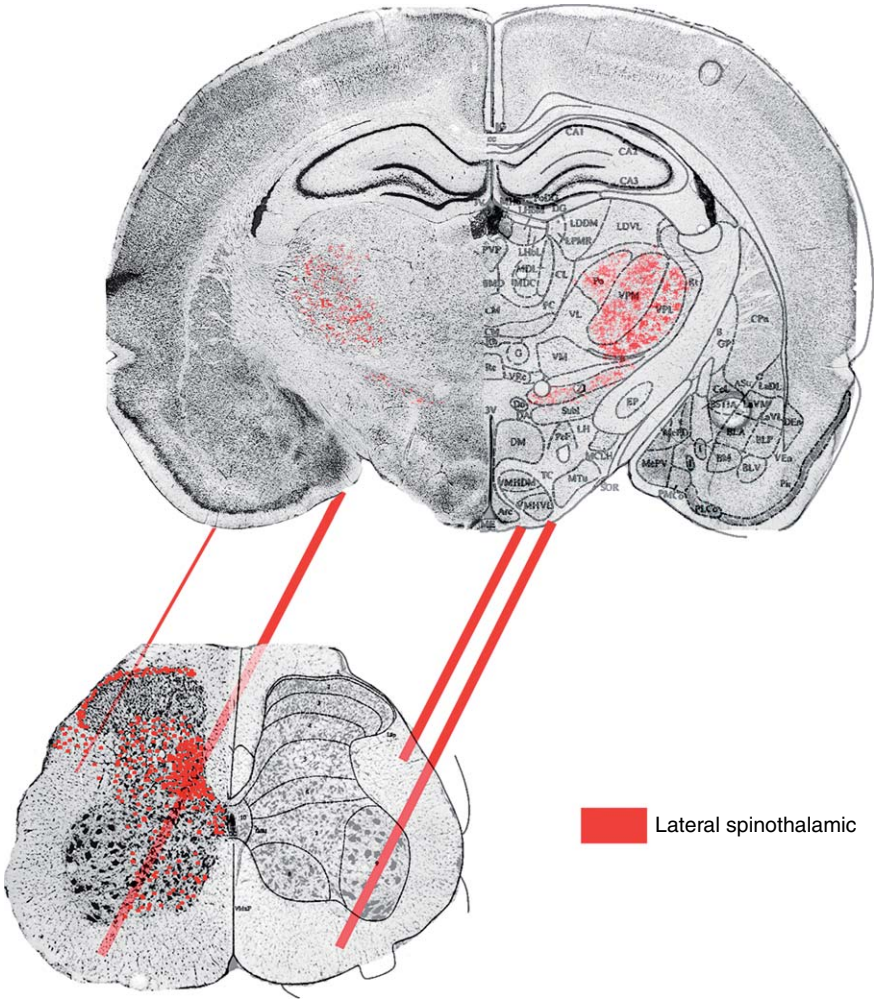

Figure 17 Diagram representing the spinal laminae of origin, ascending course in the spinal cord and areas of termination of the lateral spinothalamic pathway. Note the cluster appearance of axon termination in the VPL. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

1978b; Willis, W. D. *et al*., 1979; Giesler, G. J. *et al*., 1979a; Berkley, K. J., 1980; Leah, J. *et al*., 1988; Lima.D. and Coimbra, A., 1988; Burstein, R. *et al*., 1990b).

In laminae I and IV, a somatotopic arrangement has been described, neurons receiving input from extensor surfaces being located more laterally than neurons receiving input from flexor surfaces (Willis, W. D. *et al*., 1974). The amount of spinothalamic neurons varies considerably along the rostrocaudal extent of the spinal cord due to additional intense labeling in particular areas at various spinal levels. This is the case of the deep dorsal horn contralaterally, and the intermediate/ventral horn, bilaterally, in spinal segments C1–C2 (Carstens, E. and Trevino, D. L., 1978a; Carstens, E. and Trevino, D. L., 1978b; Giesler, G. J. *et al*., 1979a; Lima.D. and Coimbra, A., 1988; Burstein, R. *et al*., 1990b), and the intermediate basilar nucleus of Cajal, contralaterally, in the rat (Giesler, G. J. *et al*., 1979a; Lima.D. and Coimbra, A., 1988; Burstein, R. *et al*., 1990b). Due to this regional variability, together with the fact that the multiple spinal groups projecting to the lateral thalamus also project to many other supraspinal targets, the erroneous assumption that thalamic projections from certain areas, such as lamina I, to the main lateral spinal target, the VPL, are not sufficiently relevant gained credit (Blomqvist, A. *et al*., 2000; Craig, A. D. *et al*., 2002; Klop, E. M. *et al*., 2004). However, although the relative participation of lamina I neurons is below 10% in the cat (Klop, E. M. *et al*., 2004) and rat (Burstein, R. *et al*., 1990b) when the spinal cord is considered as a whole, small relative amounts are only found in segments where additional labeling occurs in particular spinal groups, as is the case of the upper cervical and lumbar cord (Burstein, R. *et al*., 1990b). Notably, in the cervical enlargement of the rat, numbers of lamina I spinothalamic neurons equal those in the deep dorsal horn (Burstein, R. *et al*., 1990b). Moreover, many lamina I neurons in the contralateral spinal and medullary dorsal horn of the monkey project to the ventrobasal complex of the thalamus, amounting to one-third of the entire dorsal horn labeled population (Willis, W. D. *et al*., 2001).

Although the spinothalamic lateral pathway is classically considered to project contralaterally except for the ventral horn in segments C_1–C_2 (Trevino, D. L. and Carstens, E., 1975; Carstens, E. and Trevino, D. L., 1978a; Carstens, E. and Trevino, D. L., 1978b; Willis, W. D. *et al*., 1979; Giesler, G. J. *et al*., 1979a), the use of very sensitive tracers such as CTb disclosed an important ipsilateral component (Lima.D. and Coimbra, A., 1988). Ipsilateral neurons amounted to about half the neurons labeled in the contralateral side in the lateral spinal nucleus and the deep dorsal horn in almost all the spinal segments examined. In the ventral horn, ipsilateral neurons equalized in number contralateral neurons, except in the cervical enlargement, where they were more abundant. Only in lamina I and the intermediate basilar nucleus of Cajal, contralateral neurons largely surpassed ipsilateral neurons. The need of using a very sensitive tracing technique to reveal the ipsilateral neuronal population suggests that these neurons may actually be contralaterally projecting neurons that send axonal collaterals to the ipsilateral thalamus. However, there is evidence from ventral spinal lesions in primates that nociceptive input is also conveyed supraspinally in the ipsilateral anterolateral quadrant (Vierck, C. J. and Luck, M. M., 1979).

The areas of spinal axon arborization in the lateral thalamus (Figure 17) were thoroughly studied in primates, including the monkey (Mehler, W. R. *et al*., 1960; Bowsher, D., 1961; Mehler, W. R., 1966; Mehler, W. R., 1969; Kerr, F. W. L. and Lippman, H. H., 1974; Boivie, J., 1979; Berkley, K. J., 1980; Mantyh, P. W., 1983a; Apkarian, A. V. and Hodge, C. J., 1989a) and humans (Mehler, W. R., 1962; Mehler, W. R., 1974). In these species, as in the rat (Lund, R. D. and Webster, K. E., 1967; Mehler, W. R., 1969; Zemlan, F. P. *et al*., 1978; Peschanski, M. *et al*., 1983; Cliffer, K. D. *et al*., 1991), the VPL is the major recipient of spinal fibers. In the VPL, spinal afferents are somatotopically arranged in rostrocaudally oriented clusters so that axons arriving from the lumbosacral spinal cord terminate in the lateral part of the nucleus and axons from the cervical enlargement terminate in the medial part (Boivie, J., 1979; Mantyh, P. W., 1983a). Such a somatotopic arrangement supports the ability of the lateral spinothalamic pathway to process spatial discrimination. Other important lateral thalamic areas of spinal termination are the posterior complex (PO), the ventral posteroinferior nucleus (VPI) and the zona incerta (ZI) ((Mehler, W. R., 1974; Boivie, J., 1979; Apkarian, A. V. and Hodge, C. J., 1989a; Cliffer, K. D. *et al*., 1991). In the cat, fibers in the lateral spinothalamic pathway appear to be fewer and terminate in the ZI, the posterior complex, and in a shell area surrounding the VPL ventrolaterally (Boivie, J., 1971; Jones, E. G. and Burton, H., 1974; Berkley, K. J., 1980; Mantyh, P. W., 1983b; Craig, A. D. and Burton, H., 1985). Recently, Craig and colleagues claimed that a region located posteromedially to the VPL,

which they called VMpo, is the site of termination of the lamina I spinothalamic fibers (Craig, A. D. *et al.*, 1994, 2002; Blomqvist, A. *et al.*, 2000). However, besides the fact that the so-called VMpo was most probably included in the area of termination of spinal and trigeminal thalamic afferents described by Mehler (Mehler, W. R., 1966) in humans, numerous retrograde and anterograde studies have proved that lamina I neurons project to many other areas in the thalamus (references given earlier), including a study by Craig (Craig, A. D., 2003) using anterograde tracing with *phaseolus vulgaris* leucoagglutinin. Moreover, this assumption was based on the dense calbindin-staining observed in the VMpo, but neither is the calbindin-immunoreactive region restricted to the VMpo lying within the medial aspect of the ventral posterior medial nucleus (Graziano, A. and Jones, E. G., 2004), nor are calbindin-immonoreactive projecting cells exclusively located in lamina I (Menétrey, D. *et al.*, 1992b).

5.35.6.1.2 Structural types of neurons involved

Spinothalamic cells were shown, in retrograde labeling studies, to have cell bodies that vary in shape from roundish or flattened to polygonal (Willis, W. D. *et al.*, 1979). They are mainly small in lamina I and include cells with fusiform, pyriform, and triangular shapes in transverse view, beyond the classic Waldeyer cells. In deep dorsal horn as well as the ventral horn, they are medium to large sized and polygonal in shape. Similar data were obtained by Apkarian and Hodge (Apkarian, A. V. and Hodge, C. J., 1989d), although in this case, tracer injections included the medial thalamus. Spinothalamic cells intracellularly stained in laminae IV–VIII of the cat (Meyers, D. E. R. and Snow, P. J., 1982) and monkey (Surmeier, D. J. *et al.*, 1988) presented long dendritic branches that could reach the lateral funiculus, lamina I and lamina X. In the intermediomedial gray matter, spinothalamic cells presented spheroidal cell bodies and narrow dendrites (Milne, R. J. *et al.*, 1982). Around the central canal, neuropeptide-containing spinothalamic cells had oval cell bodies and dendrites oriented transversely, reaching the central canal medially (Leah, J. *et al.*, 1988).

Injections of CTb confined to the VPL in the rat revealed that VPL-projecting lamina I neurons belong in the pyramidal and flattened groups (Lima.D. and Coimbra, A., 1988). Pyramidal cells prevailed over flattened cells in the cervical and lumbar enlargements (70% and 77%, respectively), the reverse occurring at C1 and C2 (40%) (Lima.D. and Coimbra, A., 1988). In the cat (Zhang, E. T. *et al.*, 1996) and monkey (Zhang, E. T. and Craig, A. D., 1997), large tracer injections filling both the lateral and medial thalamus, resulted in labeling of fusiform neurons, beyond pyramidal and flattened neurons. Although the authors explained their labeling of fusiform neurons by putative species differences, fusiform neurons were most probably labeled from the medial thalamus (see further). It should be emphasized that, in the studies by Craig and co-workers (Zhang, E. T. *et al.*, 1996; Zhang, E. T. and Craig, A. D., 1997), flattened neurons were designated 'multipolar' due to their appearance in horizontal view, on which the authors based their observations. However, this designation is misleading and should be avoided since a neuronal group completely distinct in dendritic geometry and specializations was previously designated 'multipolar' in the rat (Lima, D. and Coimbra, A., 1986), and subsequently observed in the cat (Galhardo, V. and Lima, D., 1999), monkey (Lima, D. *et al.*, 2002), and pigeon (Galhardo, V. *et al.*, 2000) as well. When compared to flattened neurons, multipolar neurons have ventrally oriented rather than horizontal dendritic arbors and highly spiny rather than smooth dendritic branches. This kind of misuse of nomenclature already led some authors to disregard the occurrence of flattened neurons as an independent group in the cat and monkey, based on the results of retrograde labeling and immunostaining (Yu, X. H. *et al.*, 1999), despite the fact that flattened neurons were clearly identified in both species by the use of Golgi impregnation (Galhardo, V. and Lima, D., 1999; Lima, D. *et al.*, 2002).

5.35.6.1.3 Spinal location of ascending fibers

Axons of the lateral spinothalamic tract travel in the ventral, ventrolateral, and dorsolateral funiculi after decussating the spinal cord within a short distance from the cell body (Applebaum, A. E. *et al.*, 1975; Willis, W. D. *et al.*, 1979; Giesler, G. J. *et al.*, 1981a; Jones, M. W. *et al.*, 1985; Surmeier, D. J. *et al.*, 1988; Stevens, R. T. *et al.*, 1989; Apkarian, A. V. and Hodge, C. J., 1989a,b). Spinothalamic axons from lamina I cells were shown to project through the dorsolateral fasciculus in the cat (Apkarian, A. V. *et al.*, 1985; Stevens, R. T. *et al.*, 1989) and monkey (Apkarian, A. V. and Hodge, C. J., 1989a,b,c). Neurons located in the deep dorsal horn and ventral horn project through the ventrolateral fasciculus and ventral funiculus (Stevens, R. T. *et al.*, 1989; Apkarian, A. V. and Hodge, C. J., 1989b; Zhang, X. J. *et al.*, 2000). In the

ventrolateral quadrant of the spinal cord white matter, axons are arranged somatotopically so that those originating in more caudal levels are located dorsolaterally to the more rostral ones (Horrax, G., 1929; Foerster, O. and Gagel, O., 1932; Hyndman, O. R. and Van Epps, C., 1939; Walker, A. E., 1940; Applebaum, A. E. *et al.*, 1975). The termination sites of the dorsolateral and ventrolateral fibers are equally distributed in the lateral thalamus, except for VPI and the ZI whose spinal afferents course mainly in the dorsolateral fasciculus and the ventral spinal quadrant, respectively (Apkarian, A. V. and Hodge, C. J., 1989a).

5.35.6.1.4 Surface receptors

Enkephalin immunoreactive varicosities were shown to establish asymmetric synaptic contacts upon medullary and spinal neurons retrogradely labeled from large HRP injections centered in the lateral thalamus of the cat and monkey (Ruda, M. A. *et al.*, 1984). These neurons make up 30% of lamina I and 50% of lamina V labeled neurons. In transverse sections, neurons present bipolar configuration in lamina I (equivalent to flattened neurons of Lima, D. and Coimbra, A., 1986) and multipolar configuration in lamina V (Ruda, M. A. *et al.*, 1984). Spinothalamic neurons exhibiting immunostaining for the NMDA receptor (Zou, X. Y. *et al.*, 2000) and metabotropic glutamate receptor subtype 1 (mGluR1) (Millis, C. D. and Hulsebosch, C. E., 2002) have been described in studies. A study focused on lamina I neurons retrogradely labeled from large injections comprising both the lateral and medial thalamus revealed NK1 receptors in flattened (called 'multipolar' by the authors) and pyramidal neurons, the latter being relatively few, however (Yu, X. H. *et al.*, 1999). This was taken as supporting the nonnociceptive nature of pyramidal neurons, although large amounts of pyramidal neurons expressing the NK1 receptor were observed by other authors (Todd, A. J. *et al.*, 2002), and pyramidal neurons are c-*fos*-activated following various kinds of noxious stimulation (Lima, D., 1998).

5.35.6.1.5 Neurotransmitters

Most studies addressing the neurochemical nature of spinothalamic neurons looked for the presence of neuropeptides in the rat. Neuropeptide-containing lateral spinothalamic neurons were preferentially observed in the lateral spinal nucleus and around the central canal (including lamina X). Both VIP (Nahin, R. L., 1988) and bombesin (Leah, J. *et al.*, 1988) were observed in the lateral spinal nucleus at the lumbar cord. In lamina X, neurons immunoreactive for bombesin (Leah, J. *et al.*, 1988), CCK (Ju, G. *et al.*, 1987; Leah, J. *et al.*, 1988), and galanin (Ju, G. *et al.*, 1987) were described. Galanin and CCK were seen to co-localize in lamina X neurons projecting to the VPL (Ju, G. *et al.*, 1987). Neurons containing glutamate or glutaminase were described in the lateral trigeminothalamic system in areas where WDR and low-threshold neurons predominate (Magnusson, K. R. *et al.*, 1987). Calbindin was claimed to be present in the majority of lamina I spinothalamic neurons of all structural groups projecting to the thalamus (Craig, A. D. *et al.*, 2002), although anterograde tracing combined with immunocytochemical staining failed to reveal calbindin-immunostaining in lamina I axons terminating in the thalamus (Graziano, A. and Jones, E. G., 2004).

5.35.6.1.6 Response properties

Spinothalamic cells were shown to present background activity at variable firing rates depending on the species and their laminar location in the spinal cord. Only few lamina I cells present background activity (Craig, A. D. and Kniffki, K. D., 1985) in the cat as compared to lamina I cells in the monkey (Ferrington, D. G. *et al.*, 1987) and to laminae IV–V cells in both species (Giesler, G. J. *et al.*, 1981b; Ferrington, D. G. *et al.*, 1986). Most spinothalamic cells respond to stimulation of C primary afferent fibers (Chung, J. M. *et al.*, 1979), but many of them respond to volleys in Aδ and Aβ fibers of somatic nerves as well (Foreman, R. D. *et al.*, 1975; Beall, J. E. *et al.*, 1977; Chung, J. M. *et al.*, 1979). Spinothalamic cells also respond to Aδ and C-fiber volleys in visceral nerves (Foreman, R. D. and Weber, R. N., 1980; Blair, R. W. *et al.*, 1981; Foreman, R. D. *et al.*, 1981, 1984; Rucker, H. K. and Holloway, J. A., 1982; Ammons, W. S., 1987) and to group II, III, and IV muscle afferents (Foreman, R. D. *et al.*, 1979). Lateral spinothalamic neurons were found to be activated by mechanical and/or thermal noxious stimulation of the skin in the rat (Giesler, G. J. *et al.*, 1976), cat (Fox, R. E. *et al.*, 1980; Ferrington, D. G. *et al.*, 1986), and monkey (Willis, W. D. *et al.*, 1974, 1979; Applebaum, A. E. *et al.*, 1975; Price, D. D. *et al.*, 1978; Kenshalo, D. R., Jr. *et al.*, 1979; Giesler, G. J. *et al.*, 1981b; Surmeier, D. J. *et al.*, 1986a,b; Ferrington, D. G. *et al.*. 1987) as well as by noxious chemical stimulation (Simone, D. A. *et al.*, 1991) and low-threshold mechanical (Willis, W. D. *et al.*, 1974; Applebaum, A. E. *et al.*, 1975; Giesler, G. J. *et al.*, 1976; Price, D. D. *et al.*, 1978) cooling

(Dostrovsky, J. O. and Craig, A. D., 1996; Craig, A. D. *et al.*, 2001) and warming (Andrew, D. and Craig, A. D., 2001) stimulation. Nociceptive neurons belong in both the NS and WDR classes (Willis, W. D. *et al.*, 1974; Giesler, G. J. *et al.*, 1981b; Ferrington, D. G. *et al.*, 1986). NS neurons are equally distributed throughout laminae I and IV–V, while WDR neurons predominate in laminae IV–V (Willis, W. D. *et al.*, 1974) and neurons responsive to cooling are located in lamina I (Craig, A. D. *et al.*, 2001). Thermal-responsive neurons belonging in either the NS or the WDR neuronal classes were shown to be capable of encoding noxious heat intensity (Figure 18) irrespective of their location in lamina I or the deep dorsal horn (Kenshalo, D. R., Jr. *et al.*, 1979; Ferrington, D. G. *et al.*, 1986; Surmeier, D. J. *et al.*, 1986a, b).

Neurons with convergent input from the skin and viscera also contribute to the lateral spinothalamic pathway (Foreman, R. D. and Weber, R. N., 1980; Blair, R. W. *et al.*, 1981; Foreman, R. D. *et al.*, 1984; Ammons, W. S. *et al.*. 1984; Ammons, W. S., 1987; Al-Chaer, E. D. *et al.*, 1999; Chandler, M. J. *et al.*, 2000). Curiously, in lamina X, neurons of the postsynaptic dorsal column tract were shown to receive viscerosomatic input and reported to be more numerous than those of the spinothalamic tract (Al-Chaer, E. D. *et al.*, 1999; Dorsal Columns and Visceral Pain).These neurons belong in the WDR, NS, or high-threshold inhibitory classes, and present cutaneous receptive fields that occupy regions to which pain is frequently referred (Foreman, R. D. and Weber, R. N., 1980; Foreman, R. D. *et al.*, 1984; Ammons, W. S. *et al.*, 1984). Some of these neurons were shown to leave axonal collaterals in the medial medullary reticular formation (Foreman, R. D. *et al.*, 1984). Some spinothalamic neurons receive convergent input from the skin and deep tissues (Willis, W. D. *et al.*, 1974; Giesler, G. J. *et al.*, 1981b; Ferrington, D. G. *et al.*, 1986). These neurons are thought to have a proprioceptive function (Milne, R. J. *et al.*, 1982). They are mainly located in the lateral part of lamina V and intermediomedial gray matter (Stilling's nucleus) and respond to either weak or intense cutaneous stimulation (Willis, W. D. *et al.*, 1974).

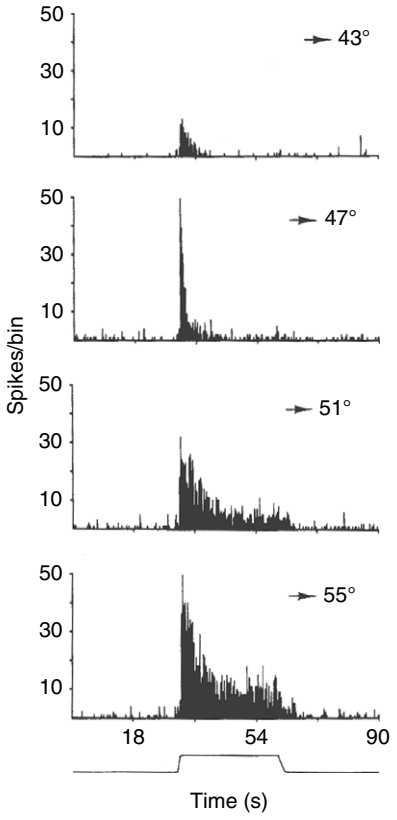

Figure 18 Responses of a lateral spinothalamic neuron to heat stimulation of increasing intensities. Adapted from figure 1 of Surmeier, D. J., Honda, C. N., and Willis, W. D. 1986a. Temporal features of the responses of primate spinothalamic neurons to noxious thermal stimulation of hairy and glabrous skin. J. Neurophysiol. 56, 351–369.

Lateral spinothalamic neurons normally present ipsilateral receptive fields that vary from very small (less than one digit) to moderate (the entire limb) (Willis, W. D. *et al.*, 1974; Giesler, G. J. *et al.*, 1981b), as well as additional inhibitory receptive fields (Gerhart, K. D. *et al.*, 1981; Giesler, G. J. *et al.*, 1981b; Ammons, W. S., 1987). In a few cells, convergent inhibitory cutaneous or visceral receptive fields were reported (Willis, W. D. *et al.*, 1974; Blair, R. W. *et al.*, 1981; Milne, R. J. *et al.*, 1982). Receptive fields tend to be smaller in high-threshold neurons and in lamina I neurons (Applebaum, A. E. *et al.*, 1975; Giesler, G. J. *et al.*, 1981b; Ferrington, D. G. *et al.*, 1987). The relatively small size of the receptive fields of lateral spinothalamic neurons favors a role in discriminating the size of the stimulated area (Giesler, G. J. *et al.*, 1981b).

C-*fos* induction after noxious cutaneous or visceral stimulation was observed in spinothalamic neurons in laminae I, III–VII, and X (Palecek, J. *et al.*, 2003). Curiously, neurons projecting in the postsynaptic dorsal column pathway were activated in similar proportions by the noxious cutaneous stimuli and in even higher proportions by the visceral stimuli (Palecek, J. *et al.*, 2003). In lamina I, both flattened and pyramidal neurons projecting to the

VPL were c-*fos*-activated following cutaneous mechanical, thermal, and chemical noxious stimulation, and, in smaller amounts, following visceral chemical stimulation (Lima, D. *et al.*, 1992; Lima, D., 1998).

5.35.6.1.7 Pathways driven at the target

The VPL is long-known for sending nociceptive input to the parietal somatosensory cortex (Burton, H. and Jones, E. G., 1976; Whitsel, B. L. *et al.*, 1978; Kenshalo, D. R., Jr. *et al.*, 1980). Combined anterograde tracing from the spinal cord and retrograde tracing from the somatosensory cortex in the monkey revealed that overlapping between spinal thalamic afferents and thalamic neurons projecting to cortical areas SI or SII occurs in the VPL, but also in the VPI and PO, the VPL being the area where the number of overlapping neurons is smaller (Stevens, R. T. *et al.*, 1993; Shi, T. and Apkarian, A. V., 1995). VPL afferents in cortical areas SI and SII are arranged in a somatotopic fashion (Burton, H. and Jones, E. G., 1976; Whitsel, B. L. *et al.*, 1978) so that the more posterior the thalamic source of afferents, the more posterior the cortical termination sites. Sparse cells in the lateral part of the VPL and the ventral part of the VPI target the cingulated cortex (Apkarian, A. V. and Shi, T., 1998).

The PO projects to the granular insular and retroinsular cortex in primates (Burton, H. and Jones, E. G., 1976) and was therefore proposed to be involved in nociceptive visceral processing (Cechetto, D. F. and Saper, C. B., 1987). PO neurons projecting to the anterior insula were seen to clearly overlap with spinothalamic axonal arborizations (Apkarian, A. V. and Shi, T., 1998). Neurons in the VPI also show insular projections, but with no overlapping. Moreover, neurons projecting to the insula do not overlap with neurons projecting to SI (Apkarian, A. V. and Shi, T., 1998).

5.35.6.2 Medial Thalamus

The medial spinothalamic pathway was described at the middle 1960s as an ascending nociceptive system especially devoted to the processing of the affective and motivational aspects of pain (Melzack, R. and Casey, K. L., 1968). While anatomical degeneration studies demonstrated the termination in medial thalamic nuclei of spinal axons ascending in the ventrolateral quadrant of the spinal cord (Bowsher, D., 1957, 1961; Mehler, W. R. *et al.*, 1960; Boivie, J., 1971), clinical studies revealed that, in patients with lesions centered in the medial thalamus, the painful poorly localized unpleasant feeling was abolished (Hécaen, H. *et al.*, 1949).

5.35.6.2.1 Spinal laminae of origin and sites of termination

Spinal neurons projecting to medial thalamic nuclei prevail in the contralateral intermediate and ventral gray matter (Figure 19) in the rat (Giesler, G. J. *et al.*, 1979a), cat (Carstens, E. and Trevino, D. L., 1978b), and monkey (Willis, W. D. *et al.*, 1979; Giesler, G. J. *et al.*, 1981b). In the cat, although a predominant location in laminae VII and VIII has been described by some authors (Carstens, E. and Trevino, D. L., 1978b; Comans, P. E. and Snow, P. J., 1981), others point to a laminar distribution similar to that observed for the lateral spinothalamic pathway, namely laminae I, IV–VI, and VII to X (Stevens, R. T. *et al.*, 1989; Craig, A. D. *et al.*, 1989). Lamina I was also shown to be the source of spinal afferents to the nucleus submedius in the cat and monkey (Craig, A. D. and Burton, H., 1981; Stevens, R. T. *et al.*, 1989) and to contribute to the spinal projections to the intralaminar complex in the monkey (Albe-Fessard, D. *et al.*, 1975; Ammons, W. S. *et al.*, 1985). In the rat, projections from laminae IV–VII were recently shown to target the central lateral nucleus, whereas the medial dorsal nucleus was found to be mainly innervated bilaterally by the lateral spinal nucleus and, to a lesser extent, by contralateral lamina I (Gauriau, C. and Bernard,J.F., 2004).

Spinal afferents ascending to the medial thalamus appear to be fewer than those reaching the lateral thalamus (Mehler, W. R. *et al.*, 1960; Apkarian, A. V. and Hodge, C. J., 1989a). They target similar medial thalamic regions in the rat (Lund, R. D. and Webster, K. E., 1967; Mehler, W. R., 1969; Zemlan, F. P. *et al.*, 1978; Cliffer, K. D. *et al.*, 1991), cat (Boivie, J., 1971; Berkley, K. J., 1980; Mantyh, P. W., 1983a; Craig, A. D. and Burton, H., 1985), monkey (Mehler, W. R. *et al.*, 1960; Boivie, J., 1979; Mantyh, P. W., 1983a; Apkarian, A. V. and Hodge, C. J., 1989a), and humans (Mehler, W. R., 1962; Mehler, W. R., 1974). These include the medial dorsal and paraventricular nuclei and the intralaminar complex, namely the central lateral, center median, paracentral, and parafascicular nuclei (Figure 19). In the monkey, the medial dorsal nucleus (except for its dorsomedial part) and the central lateral nucleus are the major sites of termination of spinal fibers (Apkarian, A. V. and Hodge, C. J., 1989a). The nucleus submedius is also a consistent site of spinal axon arborization in the cat (Boivie, J., 1971; Craig, A. D. and Burton, H., 1981; Mantyh, P.

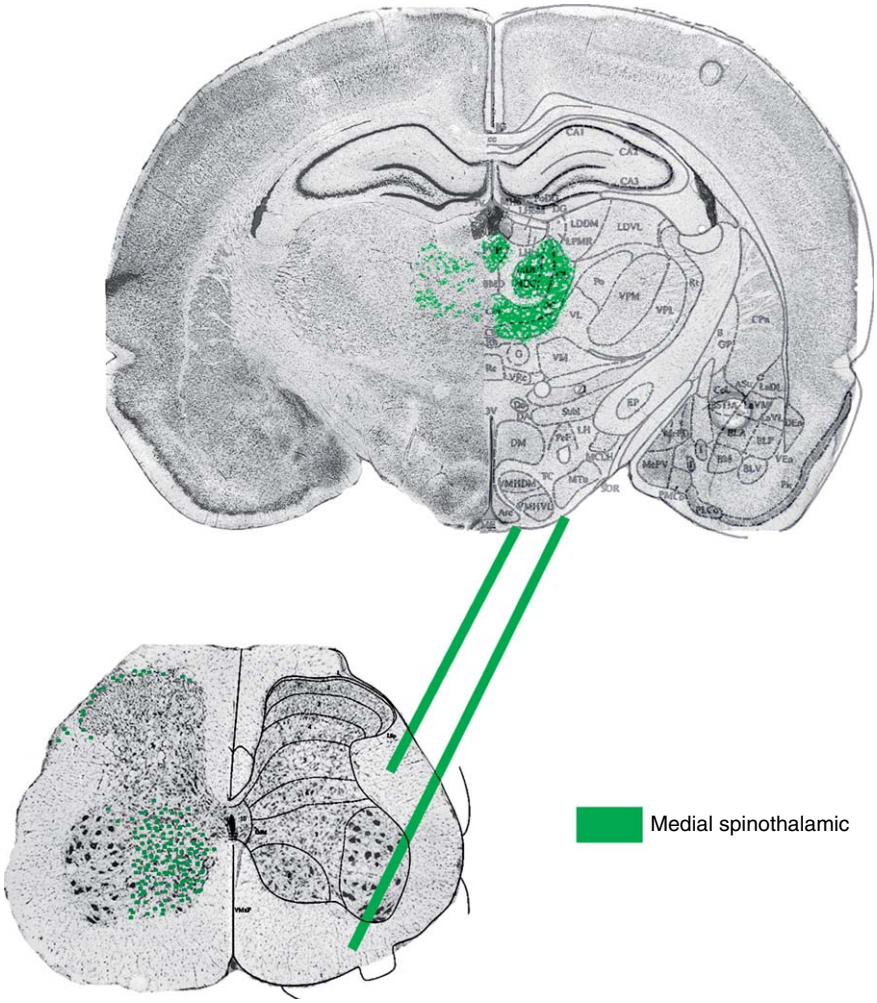

Figure 19 Diagram representing the spinal laminae of origin, ascending course in the spinal cord and areas of termination of the medial spinothalamic pathway. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

W., 1983b; Craig, A. D. and Burton, H., 1985) and monkey (Boivie, J., 1979; Mantyh, P. W., 1983a; Apkarian, A. V. and Hodge, C. J., 1989a), but in relatively small amounts (Mantyh, P. W., 1983a; Apkarian, A. V. and Hodge, C. J., 1989a).

Contrary to the lateral thalamus, no somatotopic arrangement of spinal terminals could be detected in the intralaminar complex (Boivie, J., 1979), which agrees with electrophysiological studies (Giesler, G. J. *et al.*, 1981b; Guilbaud, G. *et al.*, 1985) as to the inadequacy of the medial spinothalamic system to process information related to stimulus discrimination. In the nucleus submedius, however, a somatotopic organization was described, with fibers from more rostral spinal levels terminating more rostrally in the nucleus (Craig, A. D. and Burton, H., 1985).

5.35.6.2.2 Structural types of neurons involved

Although there are no descriptions of the morphology of spinal neurons labeled from injections restricted to medial thalamic nuclei, data on laminae VI–X spinothalamic cells revealed medium to large-sized soma of polygonal or occasionally flattened configuration (Willis, W. D. *et al.*, 1979). Following injections filling both the lateral and medial thalamus in the cat and monkey (Zhang, E. T. *et al.*, 1996; Zhang, E. T. and Craig, A. D., 1997), lamina I neurons belonging in the fusiform, pyramidal, and flattened groups were labeled. As to pyramidal and flattened neurons, the possibility that labeled neurons picked up the tracer in the lateral thalamus can not be ruled out, since they were shown to project to the VPL in

the rat (Lima, D. and Coimbra, A., 1988). Fusiform neurons, however, most probably project to medial thalamic nuclei as they could not be labeled from the VPL in the rat (Lima, D. and Coimbra, A., 1988).

5.35.6.2.3 Spinal location of ascending fibers

Spinal axons targeting the medial thalamus were early shown to course in the ventral quadrant of the spinal cord (Mehler, W. R. *et al.*, 1960; Bowsher, D., 1961; Mehler, W. R., 1969). In the rat this appears to be the way taken by all spinothalamic axons (Giesler, G. J. *et al.*, 1981a), whereas in the monkey axons were shown to distribute through the lateral funiculus also (Giesler, G. J. *et al.*, 1981b; Apkarian, A. V. and Hodge, C. J., 1989a). Studies using anterograde tracing after lesioning either the contralateral spinal ventral quadrant or the contralateral dorsolateral fasciculus (Apkarian, A. V. and Hodge, C. J., 1989a) revealed that the termination pattern of fibers coursing in both pathways is similar except for the fibers targeting the dorsolateral region of the medial dorsal nucleus, which course mostly in the ventral quadrant. The ventral quadrant also contributes with particularly large amounts of fibers to the central lateral nucleus afferents, mainly in its more anterior portion.

5.35.6.2.4 Neurotransmitters

Enkephalin (Coffield, J. A. and Miletiæ, V., 1987; Nahin, R. L., 1988) and dynorphin (Nahin, R. L., 1988) were immunodetected in deep dorsal horn and intermediate gray spinal neurons projecting to the medial thalamus. Enkephalin-immunoreactive neurons amount to 10% of the entire spinothalamic population (Coffield, J. A. and Miletiæ, V., 1987). Spinothalamic lamina X neurons immunoreactive for CCK (Ju, G. *et al.*, 1987; Leah, J. *et al.*, 1988) and galanin (Ju, G. *et al.*, 1987) are likely to terminate in the parafascicular nucleus, which was shown to contain fibers immunoreactive to both neuropeptides (Ju, G. *et al.*, 1987).

5.35.6.2.5 Response properties

Neurons projecting to the medial thalamus respond, although weakly, to activation of A (α to δ) and C primary afferent fibers with sustained afterdischarges (Giesler, G. J. *et al.*, 1981b). Their background activity is practically nil. They conduct at relatively low velocities, which amount to about half those of lateral spinothalamic neurons (Giesler, G. J. *et al.*, 1981b). Most medial spinothalamic neurons belong in the NS class (around two-third vs. one-third in the lateral spinothalamic pathway). Some are WDR neurons and a few respond to deep tissue stimulation (Giesler, G. J. *et al.*, 1981b). They normally present very large, frequently complex, receptive fields that may encompass the entire surface of the body (Figure 20).

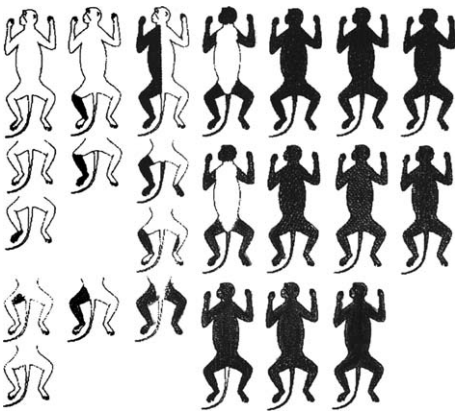

Figure 20 Receptive fields of spinal cells projecting to the medial thalamus in the monkey. Adapted from figure 3 of Giesler, G. J., Yezierski, R. P., Gerhart, K. D., and Willis, W. D. 1981b. Spinothalamic tract neurons that project to medial and/or lateral thalamic nuclei: evidence for a physiologically novel population of spinal cord neurons. J. Neurophysiol. 46, 1285–1308.

Inhibitory receptive fields are rare (Giesler, G. J. *et al.*, 1981b). Viscerosomatic convergence has been reported (Rucker, H. K. and Holloway, J. A., 1982).

5.35.6.2.6 Pathways driven at the target

Intralaminar nuclei, in particular the central lateral nucleus, project to widely distributed areas of the cerebral cortex, including sensorimotor areas, and to the basal ganglia (Jones, E. G. and Leavitt, R. Y., 1974). Ascending pathways terminating in the intralaminar nuclei have hence been proposed to be involved in motor and arousal nociceptive responses. Nociceptive pathways from the medial dorsal nucleus and the central lateral nucleus terminate, respectively, in the anterior cingulated cortex and frontal motor cortex (Wang, C. C. and Shyu, B. C., 2004). The posterior cingulated cortex also receives projections from restricted areas of both, the medial dorsal and the central lateral nuclei (Apkarian, A. V. and Shi, T., 1998). These connections are consonant with the role of the medial thalamic pathway in the emotional aspects of nociception (Wang, C. C. and Shyu, B. C., 2004). The medial dorsal nucleus and the nucleus submedius, which are similar in the response properties of their nociceptive neurons (Dostrovsky,

J. O. *et al.*, 1987), project to adjacent regions in the orbital cortex (Krettek, J. E. and Price, J. L., 1977; Craig, A. D. *et al.*, 1982; Yoshida, A. *et al.*, 1992).

5.35.6.3 Hypothalamus

5.35.6.3.1 Spinal laminae of origin and sites of termination

A direct spinohypothalamic pathway (Figure 21) was uncovered in the rat (Burstein, R. *et al.*, 1987; Burstein, R. *et al.*, 1990a; Burstein, R. *et al.*, 1990b; Menétrey, D. and DePommery, J., 1991) and cat (Katter, J. T. *et al.*, 1991) by the use of both electrophysiologic and tracing methods. It originates bilaterally, although with a slight contralateral prevalence, from the entire extent of the spinal cord (Figure 22) (Burstein, R. *et al.*, 1987, 1990a; 1990b) as well as from the spinal trigeminal nucleus, mainly the *pars caudalis* (Malick, A. and Burstein, R., 1998). Neurons in the deep dorsal horn make up the largest population of spinohypothalamic neurons, especially at upper cervical segments (around 50%), followed by the lateral spinal nucleus (around 30%), laminae I and X (around 10% each), and the intermediate ventral horn (Burstein, R. *et al.*, 1990a).

An additional contribution from the parasympathetic cell column was described in the rat (Burstein, R. *et al.*, 1990a; Menétrey, D. and DePommery, J., 1991). In the cat, the spinohypothalamic tract appears to be much smaller and to contain fewer lamina I

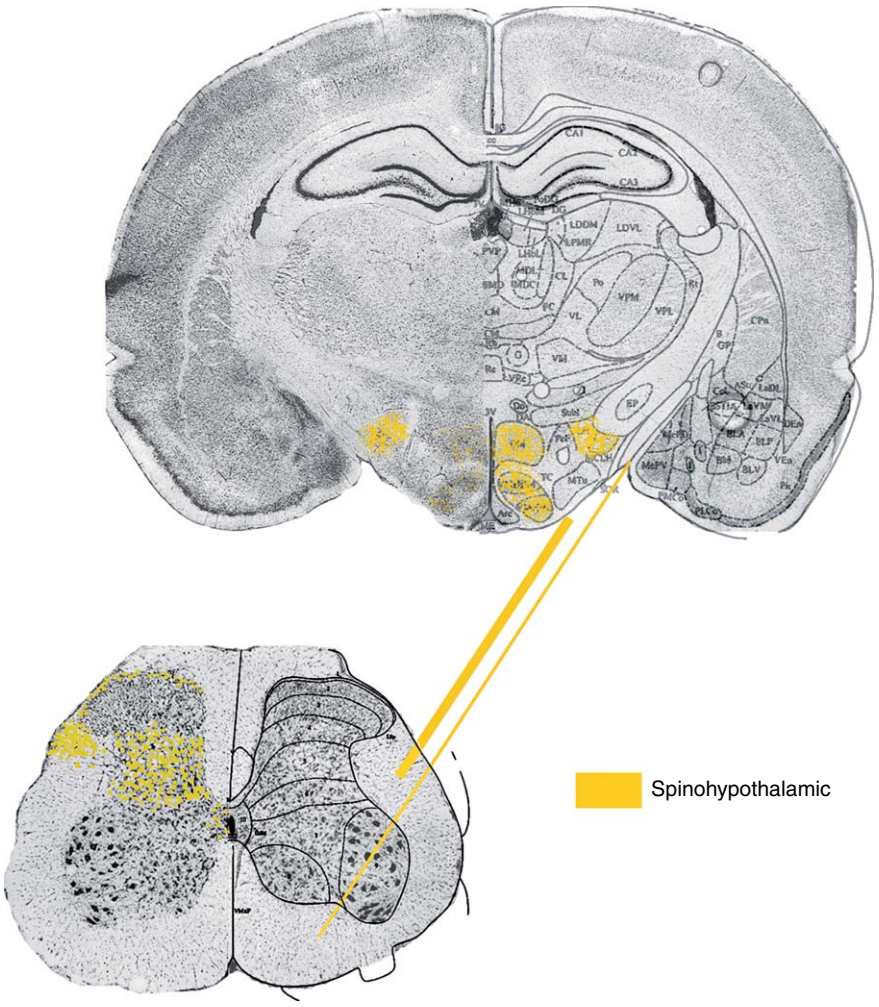

Figure 21 Diagram representing the spinal laminae of origin, ascending course in the spinal cord, and areas of termination of the spinohypothalamic pathway. Note that ipsilaterally terminating axons course contralaterally in the spinal cord. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

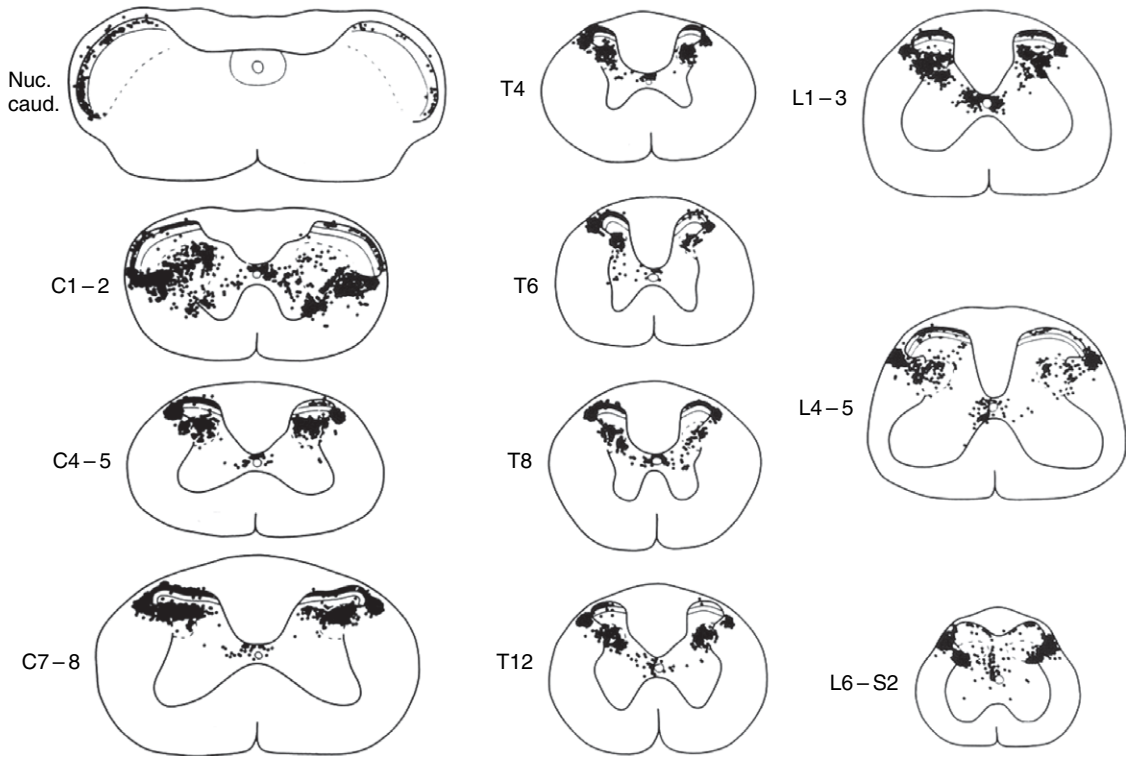

Figure 22 Distribution in the spinal cord and spinal trigeminal nucleus, *pars caudalis*, of neurons retrogradely labeled from injection of fluorogold encompassing the lateral and medial hypothalamus. (Adapted from figure 4 of Burstein, R., Cliffer, K. D., and Geisler, G. J. 1990b. Cells of origin of the spinohypothalamic tract in the rat. J. Comp. Neurol. 291, 329–344).

neurons than in the rat (Katter, J. T. *et al.*, 1991). No differences in spinal distribution were found between the medial and lateral hypothalamic pathways, except for the sacral parasympathetic nucleus, which appears to project mainly to medial nuclei (Burstein, R. *et al.*, 1990a). According to a recent study by Braz and coworkers (Braz, J. M. *et al.*, 2005) in which transgenic mice expressing a transneuronal tracer in a subset of nociceptors were used, nociceptive input conveyed by nonpeptidergic primary afferent neurons is relayed to lamina V neurons projecting to the ventromedial hypothalamus by spinal neurons located in the dorsal part of lamina II.

Consonant with retrograde and antidromic stimulation studies, terminal arborizations of spinal axons were shown to distribute massively through the lateral hypothalamus, although important labeling was also observed in the medial hypothalamus (Figure 21) (Burstein, R. *et al.*, 1987; Cliffer, K. D. *et al.*, 1991). In the lateral hypothalamus, fibers terminate bilaterally along its rostrocaudal extent, and throughout the course of the supraoptic decussation. In the medial hypothalamus, fibers terminate mainly contralaterally in the posterior and dorsal hypothalamic areas, the dorsomedial, paraventricular and suprachiasmatic nuclei, and the preoptic area (Cliffer, K. D. *et al.*, 1991). Anterograde tracer injections restricted to the superficial or deep dorsal horn confirmed that the latter contributes much more fibers to the spinohypothalamic pathway, the main areas of termination being the posterior hypothalamic area, the posterior part of the lateral hypothalamic area, and the ventral part of the paraventricular hypothalamic nucleus (Gauriau, C. and Bernard. J. F., 2004).

5.35.6.3.2 Spinal location of ascending fibers

A few studies based on degeneration following spinal lesions revealed the termination in the lateral (Anderson, F. D. and Berry, C. M., 1959; Ring, G. and Ganchrow, D., 1983) and medial (Kerr, F. W. L., 1975) hypothalamus of spinal fibers coursing in the ventral funiculus. However, electrophysiological studies using antidromic activation from the supraoptic decussation showed that only 5% of the spinohypothalamic axons course in the ventral funiculus (Burstein, R. *et al.*, 1991). The remaining travel through the lateral funiculus, mainly in the

dorsolateral fasciculus (57%), irrespective of their origin in the superficial or deep dorsal horn (Figure 21) (Burstein, R. *et al.*, 1991). Although spinal and trigeminal neurons project to the hypothalamus bilaterally, their axons ascend contralaterally in the spinal cord (Burstein, R. *et al.*, 1991) and brainstem (Kostarczyk, E. *et al.*, 1997). Those terminating ipsilaterally cross the midline within the supraoptic decussation (Burstein, R. *et al.*, 1991). Extensive collateralization along the entire brainstem has been reported (Kostarczyk, E. *et al.*, 1997).

5.35.6.3.3 Surface receptors

A particularly high number of spinal neurons projecting to the hypothalamus are apposed by profiles immunoreactive to nitric oxide synthase or to interferon-γ receptor in the lateral spinal nucleus (Kayalioglu, G. *et al.*, 1999).

5.35.6.3.4 Response properties

The majority of the neurons antidromically activated from the hypothalamus both in the spinal cord and the spinal trigeminal nucleus belong in the WDR and NS classes and also respond to noxious heat or cooling (Burstein, R. *et al.*, 1987, 1991; Malick, A. *et al.*, 2000; Zhang, X. J. *et al.*, 2002). Incremental responses to increasingly intense noxious heat stimulation were observed (Burstein, R. *et al.*, 1987). Low-threshold neurons make up 20% of the trigeminohypothalamic neurons (Malick, A. *et al.* 2000) and only 4% of the spinohypothalamic neurons (Burstein, R. *et al.*, 1991). The cutaneous receptive fields are particularly small indicating that this pathway may convey relatively precise information about the stimulated area (Burstein, R. *et al.*, 1991; Malick, A. *et al.*, 2000). About half of the spinohypothalamic neurons recorded in the thoracic spinal cord were activated by visceral distension with responses that increased with increasing stimulus intensities (Zhang, X. J. *et al.*, 2002). Eight percent of lumbar spinohypothalamic neurons respond to deep low-threshold input (Burstein, R. *et al.*, 1991).

5.35.6.3.5 Pathways driven at the target

Projections from the hypothalamus, namely the dorsomedial nucleus, descend through a dorsal pathway to the PAG, and through a ventral smaller pathway to the NTS (Thompson, R. H. *et al.*, 1996). According to c-*fos* studies (Snowball, R. K. *et al.*, 2000), neurons projecting to the ventrolateral PAG receive visceral input in the lateral hypothalamus, presumably in convergence with somatic input, and neurons projecting to the NTS are concentrated in the posterolateral hypothalamus and the paraventricular nucleus. Projections connecting the paraventricular nucleus with the ventrolateral medulla were also reported (Hardy, S. G. P., 2001).

5.35.7 Spinothelencephalic Pathways

During the last decade, evidence accumulated about the existence of ascending nociceptive pathways that connect the spinal cord directly with various telencephalic regions in the rat. Although data are mainly based on anatomic retrograde and anterograde tracing studies, both the location of the spinal cells of origin, the demonstration of cells responding to noxious stimulation in areas such as the amygdala (Miyagama, T. *et al.*, 1986), and a recent study using genetic-controlled transneuronal tracing initiated in IB4-positive putative nociceptive primary afferent fibers (Braz, J. M. *et al.*, 2005) suggest that some of these areas are spinal targets of nociceptive input.

The data on spinotelencephalic pathways collected till the early years of 2000 are still few and each study deals with several systems. Therefore, notwithstanding their probable functional individuality, they will be described together although tentatively grouped according to their putative functions.

5.35.7.1 Thelencephalic Targets of Spinal Ascending Fibers

Studies using very sensitive anterograde tracers, such as *phaseolus vulgaris* leucoagglutinin or dextran (Burstein, R. *et al.*, 1987; Cliffer, K. D. *et al.*, 1991; Gauriau, C. and Bernard J. F., 2004), revealed axonal terminal arborizations in various regions of the basal forebrain and cortex (Figure 23), which can be grouped as areas involved in motor control and areas of the limbic system.

The first group includes the globus pallidus, substantia nigra, and nucleus accumbens, in particular its medial part. A participation in the striatopallidal system as well as a role in innate motor patterns triggered by noxious stimuli has been proposed for the spinal–globus pallidus projection (Braz, J. M. *et al.*, 2005). Limbic spinal targets include nuclei of the septal complex, thought to be involved in motivation and emotion, but also in attention, arousal, learning, and memory (Burstein, R. *et al.*, 1987; Cliffer, K. D.

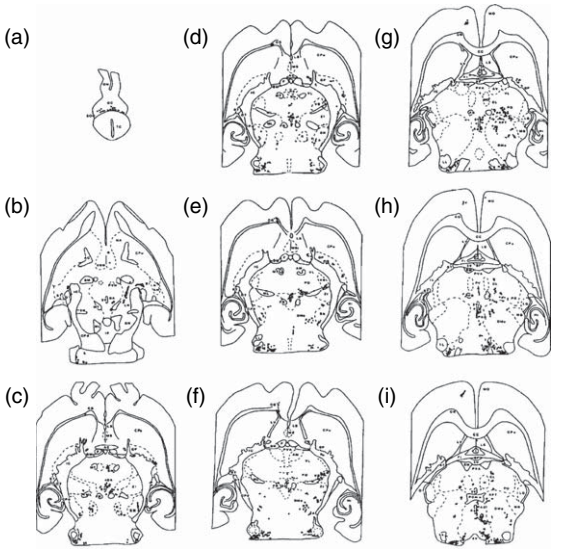

Figure 23 Distribution of spinal fibers labeled anterogradely with *phaseolus vulgaris* leucoagglutinin in the diencephalon and telencephalon, in horizontal view. Adapted from figure 3 of Cliffer, K. D., Burstein, R., and Giesler, G. J. 1991. Distributions of spinothalamic, spinohypothalamic, and spinotelencephalic fibers revealed by anterograde transport of PHA-L in rats. J. Neurosci. 11, 852–868.

et al., 1991). Positive and negative reinforcement associated with learning trials during nociceptive processing have been claimed to be accomplished by this pathway (Cliffer, K. D. *et al.*, 1991). The central nucleus of the amygdala together with what has been called the 'extended amygdala', namely the substantia innonimata and the Bed Nucleus of the stria terminalis, also receive direct projections from the spinal cord (Cliffer, K. D. *et al.*, 1991; Gauriau, C. and Bernard.J.F., 2004), as do the medial orbital and infralimbic cortices (Cliffer, K. D. *et al.*, 1991). Projections to the orbital cortex may affect autonomic, endocrine, and behavioral functions in relation to pain (Burstein, R. and Potrebic, S., 1993). The horizontal and vertical limbs of the diagonal band of Broca are also targeted by spinal axons (Burstein, R. *et al.*, 1987; Cliffer, K. D. *et al.*, 1991).

These direct spinotelencephalic projections appear to be paralleled by ascending polysynaptic pathways relaying not only in the brainstem, as is the case of the spinoparabrachialamygdaloid pathway (Ma, W. and Peschanski, M., 1988; Bernard, J. F. and Besson, J. M., 1990; Jasmin, L. *et al.*, 1997), but also within the telencephalon. Anterograde tracer injections in the central and basolateral anterior nuclei of the amygdala revealed projections from there to the substantia innonimata and stria terminalis as well as the posterior hypothalamus (Bourgeais, L. *et al.*, 2001a).

5.35.7.2 Spinal Laminae of Origin

Based on anterograde labeling from restricted injections in various spinal laminae, Gauriau and Bernard (Gauriau, C. and Bernard. J. F., 2004) concluded that cells of origin of spinopallidal fibers are located in the deep dorsal horn, laminae VII and X and, in smaller amounts, in the superficial dorsal horn (Table 1). Marked labeling was obtained in the lateral aspect of the globus pallidus from neurons located in lamina V, as revealed by transneuronal tracing with wheat germ agglutinin synthesized by IB4-positive primary afferents in mice (Braz, J. M. *et al.*, 2005).

Spinal fibers projecting to the nucleus accumbens and the septal nuclei have similar bilateral origins at the reticulated portion of the deep dorsal horn, the lateral spinal nucleus, and lamina X throughout the entire length of the spinal cord (Burstein, R. and Giesler, G. J., 1989). Deep dorsal horn neurons account to half of the entire projection population, followed by the lateral spinal nucleus, and lamina X (about 15% each). Neurons in lamina I and the intermediate/ventral horn are very few, but the first are slightly more numerous in the spinoseptal pathway (Table 1).

Spinal neurons projecting to the amygdala present similar laminar distribution (Menétrey, D. and DePommery, J., 1991; Burstein, R. and Potrebic, S., 1993). Neurons in the reticulated region of the deep dorsal horn also make up about half of the entire spinoamygdala population, but they are located in its dorsal portion in cervical segments and ventral portion in thoracolumbar segments. The lateral spinal nucleus contributes to 25% of the projection, lamina X to 13% (mainly at upper lumbar segments), and the intermediate and ventral horn to 10%, at upper cervical and lumbar segments (Table 1). Neurons in lamina V receiving primary afferent input through lamina II neurons activated by IB4-positive primary afferents also send projections to the amygdala, as well as to the bed nucleus of stria terminalis (Braz, J. M. *et al.*, 2005). A projection to the dorsal part of substantia innonimata from the superficial and deep dorsal horn, contralaterally, and from the lateral spinal nucleus, ipsilaterally, has been described (Gauriau, C. and Bernard. J.F., 2004).

Table 1 Relative participation of spinal cord laminae in the various nociceptive ascending pathways

	LSN	*I*	*II*	*III*	*IV*	*V*	*VI*	*VII*	*VIII*	*X*
LCN		■		■ (10%)	■ (60%)	■	■	■		
VLMlat	■	■	■	■						■
LRt					■	■	■	■	■	■
DRt dorsal		■ (Medial)	■ (Medial)	■ (Medial)						■
DRt ventral					■ (Medial)	■ (Medial)	■ (Medial)	■		■
NTS	■	■			■	■	■	■		■
RVM						■		■	■	■
PBN		■ (Lateral)				■ (Lateral)			■	■
PAG	■	■			■ (Lateral)	■ (Lateral)	■	■	■	■
Lateral thalamus	■	■			■	■	■	■	■	■
Medial thalamus	■	■						■	■	
Hypothalamus	■ (30%)	■ (10%)			■ (----------50%----------)					■ (10%)
N. Pallidus		■			■	■	■	■		■
N. Accumbens	■ (25%)				■ (----------50%----------)					■ (10%)
Septal nucleus	■ (15%)	■			■ (----------50%----------)					■ (15%)
Amygdala	■ (25%)					■ (-----50%-----)		■ (–10%–)	■	■ (10%)
Subst. inonimata					■	■	■			
Orbital cortex	■ (15%)					■ (-----62%-----)	■	■ (–13%–)	■	■ (10%)

Relative amounts refer to each pathway and do not allow comparisons between pathways. Whenever quantified, the relative contribution to each pathway is referred between brackets. LSN, lateral spinal nucleus; LCN, lateral cervical nucleus; VLMlat, caudal ventrolateral reticular formation, lateral portion; LRt, lateral reticular nucleus; DRt dorsal, dorsal reticular nucleus, dorsal portion; DRt ventral, dorsal reticular nucleus – ventral portion; NTS, nucleus tractus solitarii; RVM, rostral ventromedial medulla; PBN, parabrachial nuclei; PAG, periaqueductal gray; I–X, spinal laminae.

The orbital cortex receives its major spinal projections from the contralateral reticulated area of the deep dorsal horn (62%) at the cervical level or its ventromedial aspect at the thoracic and lumbar levels. The lateral spinal nucleus contributes to 15% of the projection, but mainly at lumbar segments, while the intermediate/ventral horn and lamina X contribute to 13% and 10%, respectively, both at the upper cervical and lower thoracic/upper lumbar segments (Table 1) (Burstein, R. and Potrebic, S., 1993).

5.35.8 Discussion

5.35.8.1 Multiple Parallel Ascending Pathways

The main feature that stands out is the multiplicity of the ascending nociceptive system in terms of the variety of supraspinal regions that are targeted (Figure 24). This has been interpreted as the anatomical substrate for the triggering of a multitude of responses to the noxious event, from autonomic and motor reactions to affective and cognitive behaviors. Nevertheless, it is curious to note that, contrary to what was thought in the middle of the twentieth century, nociceptive input does not necessarily arrive to high processing motor, affective, and cognitive centers in the thelencephalon through multisynaptic chains capable of filtering information at various successive levels, but can reach those areas through direct spinofugal pathways.

Another aspect that emerges is that multiple polysynaptic pathways seem to parallel monosynaptic connections between the spinal cord and each supraspinal target. So far, this organization pattern was demonstrated only for a few systems, such as the medial paracentral spinothalamic and the spinoamygdaloid

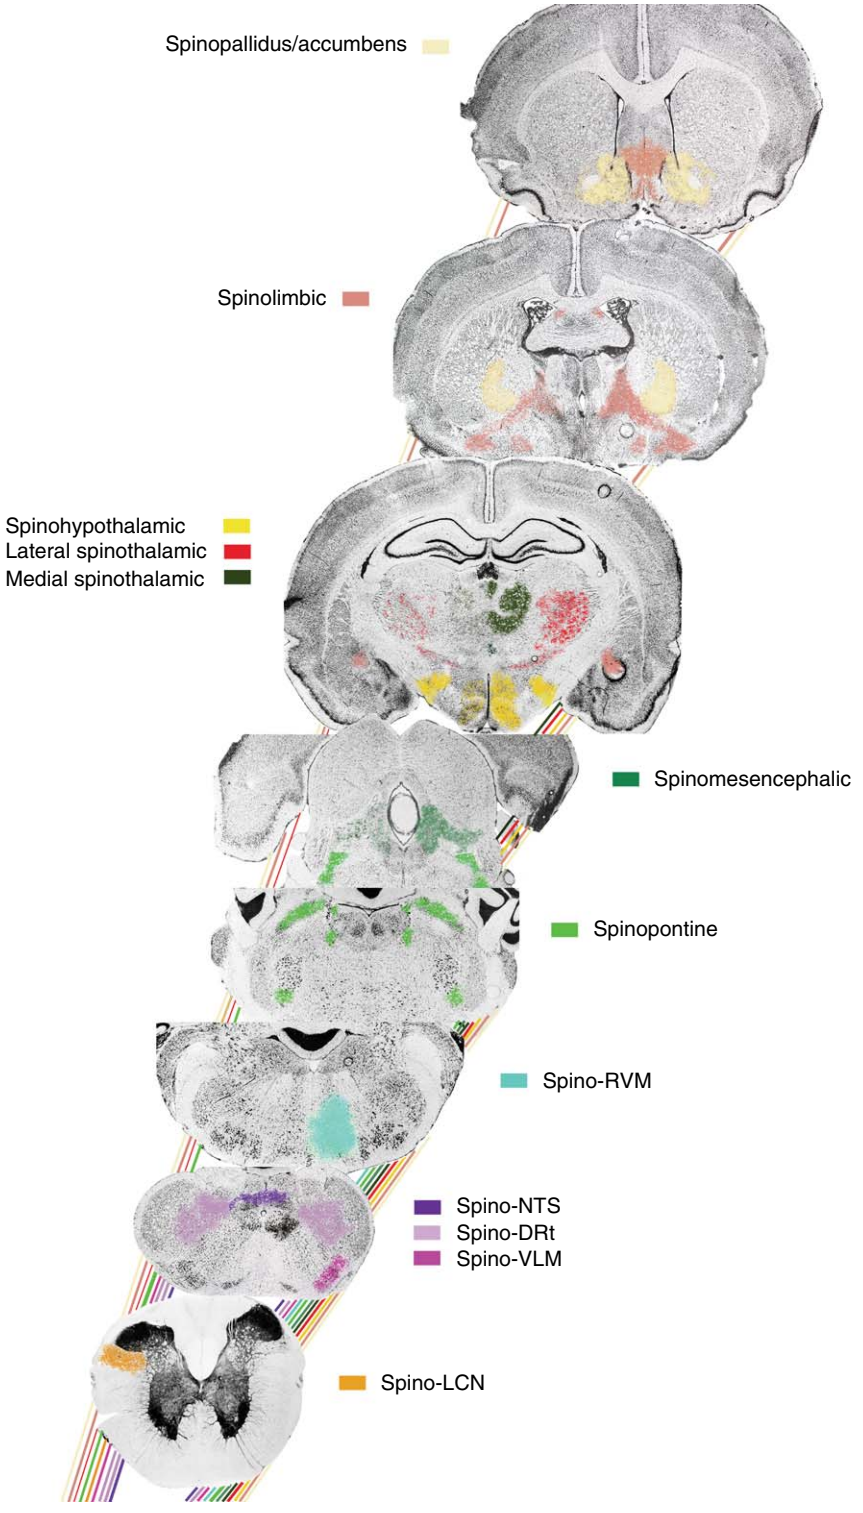

Figure 24 Diagram illustrating the termination areas of the various ascending nociceptive pathways. The laterality of the ascending tracts and termination fields with respect to the side of arrival of primary afferent input is represented, the left side being ipsilateral and the right side contralateral. Brain and spinal cord photomicrographs were adapted from Paxinos, G. and Watson, C. 1998. The Rat Brain in Stereotaxic Coordinates, 4th edn. Academic Press.

systems, served by a direct pathway and a disynaptic pathway with a relay in the PBN (Ma, W. and Peschanski, M., 1988; Bernard, J. F. and Besson, J. M., 1990; Jasmin, L. *et al.*, 1997). However, the fact that most spinal targets send projections to other brain areas that are also targeted by spinal fibers strongly suggests a similar architecture for most systems, with the participation of parallel monosynaptic and multisynaptic chains of different lengths. Such an arrangement may imply that the responses to the noxious event generated at each site evolve along time according to postarriving of noxious-evoked input generated in other pain-processing centers. Notwithstanding the extensive anatomical and electrophysiological data that are still needed to corroborate this hypothesis, it is worth to take it into consideration in future investigation.

5.35.8.2 Spinal Neuronal Populations at the Origin of Nociceptive Ascending Pathways

When facing such a variety of nociceptive ascending pathways, it is tempting to assume that they differ by either channeling different sensory modalities to brain regions specifically dedicated to their processing, or by the responses they induce to whatever stimulus through activation of a particular supraspinal region. For the first assumption to be correct, the spinal source of input should differ between different pathways. The overview of the ascending nociceptive system here presented clearly shows that this is not the case. On the contrary, if one compares the contribution of the various spinal laminae to each pathway (Table 1), the first emerging picture is that of a strong similarity, which favors the second assumption that the functional properties of a pathway depend on the functional engagement of its target. However, in spite of a large overlap, there are subtle dissimilarities between pathways consisting of a preponderance of some laminae over others or differences in the location of the projecting neurons in each lamina (Table 1). Also the electrophysiological response properties of spinal neurons participating in the various pathways overlap considerably (Table 2): all pathways including nociceptive specific, wide-dynamic-range and low-threshold neurons, as well as neurons responding to cutaneous, visceral, and deep noxious stimuli. Again, subtle differences are likely to occur about the proportion of neurons of each kind that take part in each pathway (Table 2). Differences between pathways over the amount of projecting neurons they involve have also been pointed out (Apkarian, A. V. and Hodge, C. J., 1989d; Burstein, R. *et al.*, 1990b; Mouton, L. J. and Holstege, G., 1998; Willis, W. D. *et al.*, 2001) but a complete picture of the quantitative variations is still hard to attain due to the use of tracers of variable sensitivity. As to the possibility that each pathway identity relies on a particular neurochemical architecture at the spinal relay, data are too scarce to allow any sort of considerations.

Table 2 Relative participation of low threshold (LT), wide-dynamic-range (WDR) and nociceptive specific (NS) spinal cord neurons in the various nociceptive ascending pathways

	LT	*WDR*	*NS*
LCN	Mainly hair movement	60–86%	
VLM	25%	25%	50%
NTS	+	The majority	
RVM	+	The majority	
PBN	−	+	+ (75–90% in lamina I)
PAG	+ (DDH)	50% (Lamina I + DDH	+ (lamina I)
Lateral thalamus	+	+	35%
Medial thalamus	+	+	70%
Hypothalamus	4%	The majority	

DDH, deep dorsal horn. Other abbreviations as in Table 1.

The difficulty in concealing this anatomofunctional organization with the well-known capacity of modality discrimination during acute physiological pain led some authors to ascribe discrimination capacity to a particular spinal region, leaving the remaining spinal cord with a secondary, largely unknown but eventually not important role in pain processing. The high concentration of nociceptive specific neurons in lamina I, together with the convergence of input of various nature and peripheral origin to this lamina and the easy separation of its structural neuronal groups (see Chapter Spinal Cord Physiology of Nociception) brought it into focus during the last decade. However, lamina I does not contribute to all spinofugal nociceptive pathways while participating similarly in many others (Table 1). Moreover, an appraisal of the participation of the various lamina I structural cell groups in a sample of nociceptive ascending pathways revealed

Table 3 Relative amounts of supraspinally projecting lamina I neurons

	Fusiform	*Flattened*	*Pyramidal*	*Multipolar*
VLM	80%	10%	10%	
DRt		10–30%	5–20%	60–85%
NTS	25%	40%	35%	
PBN	70%		30%	
PAG	30%		70%	
Thalamus VBC		25–30% (enlargements)	70–75% (enlargements)	

VBC, ventrobasal complex of the thalamus.

large superposition, although again slight differences as to their relative amount in each pathway and the specific involvement or noninvolvement of certain groups were detected (Table 3). What is noteworthy is that when taken together, the various electrophysiological studies on the response properties of lamina I neurons do not support a clear-cut structural–functional correlation based on stimulus-modality processing (see discussion in Galhardo, V. *et al*., 2000). The possibility that stimulus characterization at the central nervous system depends on a combinatory activation process rather than on the activation of specific channels should be addressed in the future.

As a working hypothesis, it could be postulated at this point that each pathway has particular characteristics that depend on both, the kind of input it transmits (defined by the relative contribution of the various spinal neurons) and the functional properties of the target. Ultimately, for each noxious event, ascending transmission of nociceptive input would be the result of the relative activation of the various pathways.

5.35.8.3 Stimulus Discrimination

A clear separation between the lateral and the medial spinothalamic nociceptive pathways as to the ability of the former to discriminate between stimulus location and intensity has been established, based mainly on the electrophysiological properties of neurons projecting in each pathway. Amongst the supporting data stand out the relatively small size of the receptive fields, the stimulus intensity-encoding capacity, and the somatotopic organization of the spinal, thalamic, and cortical neurons in the lateral pathway, as opposed to the medial pathway. It should be noted, however, that early studies pointed out that the medial spinothalamic system conveys spinal input either directly or through a brainstem relay, but spinal neurons projecting to brainstem regions connected to the medial thalamus do not necessarily share the same properties of the medial spinothalamic neurons. Receptive fields of spino-RVM and spino-PAG neurons vary from small, confined to a sole limb, to very large and complex. PBN-projecting spinal neurons were shown to present small receptive fields (Bester, H. *et al*., 2000), contrary to PBN neurons projecting to the paracentral nucleus of the thalamus, which have large receptive fields (Bourgeais, L. *et al*., 2001b). Also noteworthy in this respect is the fact that neurons in the RVM and PAG send axonal collaterals to the lateral thalamus, while neurons projecting through the lateral spinothalamic or the spinocervical pathways send collaterals to the medial thalamus. As a whole, the data suggest that, although the lateral spinothalamic pathway as well as the spinocervical and the spinohypothalamic pathways appear to be morphofuntionally organized to allow stimulus location and intensity discrimination, an extensive cross-talk between the various nociceptive ascending pathways is likely to take place.

5.35.8.4 Nociceptive Ascending Pathways as Part of a Complex Nociceptive Integration System

Although the ascending transmission system and the descending endogenous pain control system (see Chapter Descending Control Mechanisms) are normally dealt with separately, evidence has been accumulated to prove that they are both part of a sole nociceptive system buildup in such a way that information is treated at different brain levels in order to integrate nociception and various brain functions. The brain areas of termination of the ascending nociceptive pathways are those and the same from where pain-control actions are elicited upon local stimulation (Jones, S. L., 1992). These areas are intimately connected with each other, and

each of them with the spinal cord dorsal horn, in most cases through direct descending projections that very often participate in spino-brain-spinal reciprocal loops (Lima, D. *et al*., 1998). Descending pain-control actions appear to be triggered not only by arriving of nociceptive input, but also by the current state of processing of other functions carried out at those brain areas, as blood pressure variations at the caudal ventrolateral reticular formation (Tavares, I. and Lima, D., 2002).

The so-called ascending and descending systems are arranged as an intricate network of neuronal pathways that interchange information and dynamically control, through modulation of spinal dorsal horn activity, the level of activation of the perception and response centers. Pain perception and pain reactions are thus adapted to autonomic, affective, and cognitive states, which in turn are short- or long-term modified in response to the noxious event. The various nociceptive ascending pathways must not be viewed as static separate lines that allow the passage of nociceptive signals to distinct brain regions, but rather as an ensemble of spinal transmission neurons that tune pain perception and reactions according to peripheral and central conditions through a constant and dynamic interplay with the brain.

Glossary

activity box Apparatus used to determine the amount and time course of exploratory activity of an animal, such as a rat.

central neuropathic pain pain that develops following injury to the central nervous system.

CNQX 6-cyano-7-nitroquinoxaline-2,3-dione, a non-*N*-methyl-D-aspartic acid receptor antagonist.

kainic acid lesion damage produced by injection of kainic acid, a substance that produces excitotoxicity.

NMDA *N*-methyl-D-aspartic acid.

pain referral Projection of the source of pain to an area of the body distant to the actual area of injury.

paresthesias Unusual sensations, such as tingling or burning.

rhizotomy Transaction of one or more spinal roots.

viscerospecific responses Neuronal activity evoked by sensory input from a particular visceral organ.

5.36.1 Clinical Evidence Concerning Spinal Cord Pathways That Signal Visceral Pain

5.36.1.1 Spinothalamic Tract

5.36.1.1.1 Anterolateral cordotomy

It is well known that ascending pathways in the anterolateral quadrant of the human spinal cord transmit pain and temperature signals, since pain is relieved (at least temporarily) and thermal sense is lost over the appropriate part of the contralateral body following an anterolateral cordotomy (Spiller, W. G., 1905; Spiller, W. G. and Martin, E., 1912; Foerster, O. and Gagel, G., 1932; reviewed in Gybels, J. M. and Sweet, W. H., 1989). The signals are transmitted from one side of the body to the contralateral thalamus (Kenshalo, D. R. *et al.*, 1980; Chung, J. M. *et al.*, 1986; Bushnell, M. C. *et al.*, 1993; Lee, J. I. *et al.*, 1999; 2005) and from there to the appropriate regions of the cerebral cortex (see Casey, K. L. and Bushnell, M. C., 2000). It has been presumed that the pain signals are conveyed chiefly by the spinothalamic tract, which decussates at the spinal cord level (Mehler, W. R., 1962), although other pathways that accompany the spinothalamic tract are also likely to contribute. These include the spinoreticular, spinoparabrachial, spinohypothalamic, and other tracts (Willis, W. D. and Westlund, K. N.,1997; Willis, W. D. and Coggeshall, R. E., 2004). Innocuous thermal signals are attributed just to the spinothalamic tract.

Anterolateral cordotomy can relieve superficial and deep somatic pain, as well as visceral pain (and can block thermal sense), provided that the lesion is extensive enough (Gybels, J. M. and Sweet, W. H., 1989; Nathan, P. W. *et al.*, 2001). For complete pain relief on the contralateral side of the body, a cordotomy at an upper cervical level needs to extend from just posterior to the denticulate ligament, across the remainder of the lateral funiculus and well into the anterior funiculus (Figure 1(a); Nathan, P. W. *et al.*, 2001).

However, even after an initially successful cordotomy, pain relief may not persist more than a few months to a year or so, although in some cases the pain relief is of very long duration (Gybels, J. M. and Sweet, W. H., 1989). It is unclear why the pain can recur. Some suggestions are that other pathways now convey the pain signals, the disease advances (e.g., metastatic cancer may activate spinothalamic neurons whose axons were not interrupted by the cordotomy), or central neuropathic pain develops. Because of the recurrence of pain after a large proportion of cordotomies, neurosurgeons have tended to limit the use of this procedure to patients with pain from a terminal disease, usually cancer, or to abandon the procedure altogether in favor of pharmacotherapy.

Visceral pain can be relieved by cordotomy, provided that the lesion extends into the anterior funciculus medially to the spinal cord gray matter (Gybels, J. M. and Sweet, W. H., 1989). A unilateral cordotomy can be effective if the visceral pain is

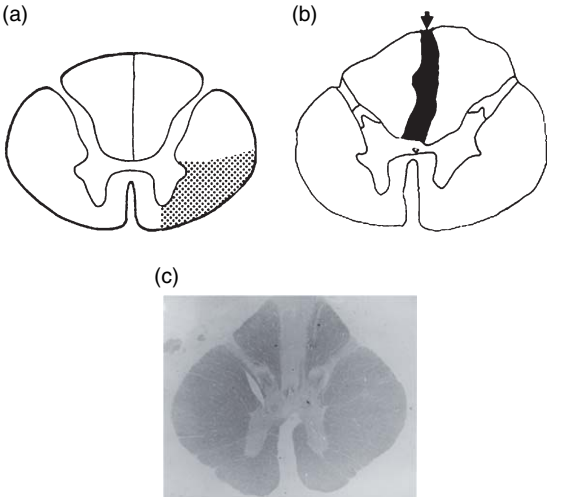

Figure 1 (a) Drawing of a cross section of the human spinal cord at the third cervical level. The dotted area shows the region that needs to be sectioned by a cordotomy in order to relieve contralateral pain completely. Note that the lesion must extend to a level that is posterior to the expected location of the denticulate ligament and anteromedially across the lateral funicuclus and into the anterior funiculus. (b) Drawing of a cross section of the human spinal cord at a mid-thoracic level showing the location of a limited midline myelotomy that was used to relieve completely the pain of colon cancer for the duration of the 3-month survival period. No opioid analgesics were required after a tapering-off period. (c) Photomicrograph of a cross section of the human spinal cord at the level of a limited midline myelotomy that was placed at a mid-thoracic level in a patient with a painful presacral sarcoma. The lesion (shown by the area of demyelination near the midline of the dorsal columns) eliminated the pain and the need for narcotics for the duration of the patient's survival time, which was 3 years postsurgery. (a) From Nathan, P. W., Smith, M., and Deacon, P. 2001. The crossing of the spinothalamic tract. Brain 124, 793–803. (b) From Hirshberg, R. M., Al-Chaer, E. D., Lawand, N. B., Westlund, K. N., and Willis, W. D. 1996. Is there a pathway in the posterior funiculus that signals visceral pain? Pain 47, 291–305.

restricted to one side. However, if the pain is bilateral, a bilateral cordotomy may be needed. Unfortunately, this can lead to undesired side effects, such as incontinence because of interruption of descending pathways that control bowel and bladder function. If the cordotomy is done at a high cervical level for pain originating from the upper part of the body, there is danger that the respiratory control pathways may be interrupted, leading to severe (potentially lethal) difficulty with breathing.

5.36.1.1.2 Commissural myelotomy

An alternative procedure called commissural myelotomy is directed at interrupting the axons of spinothalamic tract neurons of both sides as they cross the midline (Armour, D., 1927; Mansuy, L. *et al*., 1944; 1976; see Gybels, J. M. and Sweet, W. H., 1989). A lesion is made near the midline of the spinal cord and extending rostrocaudally for as many segments as needed to interrupt the appropriate projections. The lesion should be sufficiently deep to ensure that the crossing spinothalamic axons in the anterior white commissure are cut. Of course, the crossing axons of a number of tracts that accompany the spinothalamic tract, such as spinoreticular axons, are also interrupted, as are many axons in the posterior funiculi. According to the analysis of Dargent, M. *et al.* (1963), this procedure is apparently particularly effective for vaginal and visceral pain. Interestingly, commissural myelotomy often relieves clinical pain even if on testing there is no hypalgesia. Furthermore, pain and temperature sensation may be lost over a much greater extent of the body than could be predicted from the location and dimensions of the commissural myelotomy (Gybels, J. M. and Sweet, W. H., 1989). Based on evidence reviewed in the following, it now seems likely that the effect of a commissural myelotomy depends at least in part on the interruption of a visceral pain pathway that ascends in the posterior funiculi.

5.36.1.2 Posterior Column

5.36.1.2.1 Hitchcock procedure (stereotactic C1 central myelotomy)

Hitchcock developed a completely different approach to lesioning the spinal cord to relieve pain (Hitchcock, E., 1970; 1974; 1977; see also Papo, L. and Luongo, A., 1976; Eiras, J. *et al*., 1980; Schvarcz, J. R., 1977; 1978; Sourek, K., 1985). He placed a lesion in the central part of the upper cervical spinal cord using a stereotactic approach. The location of the lesion was sometimes determined by recordings of evoked potentials but more often by the sensory effects of electrical stimulation through the electrode and by the changes in the sensory examination produced by a lesion. Stimulation in the central cord at C1 at 50 Hz typically resulted in a burning sensation in the chest or abdomen (Hitchcock, E., 1970; see Gybels, J. M. and Sweet, W. H., 1989). A lesion in the same location produced a change in pinprick sensation, either a loss of the ability to distinguish sharp from blunt or loss of a sensation of pain in response to pinprick. The analgesia was bilateral. Cancer pain was relieved in most cases, and the relief persisted until death or for over 5 years. Some patients (20%) failed to have a sensory loss and also did not experience pain relief.

In the surgical series done by Schvarcz J. R. (1977; 1978), lesions were made at a depth of 5 mm from the posterior surface of the spinal cord, reaching the base of the posterior column. Electrical stimulation produced paresthesias in the feet, legs, or trunk (and also in the trigeminal distribution). Relief of cancer pain persisted in 78% of cases for at least 0.5–2 years (most of the patients died by this time). Other types of pain, including peripheral and central neuropathic pain, were relieved for 0.5–4 years. No neurological deficits were seen. Several other clinical studies reported similar results (Papo, L. and Luongo, A., 1976; Eiras, J. *et al*., 1980; Sourek, K., 1985).

5.36.1.2.2 Limited midline myelotomy

Instead of a lesion at an upper cervical level, Gildenberg P. L. and Hirshberg R. M. (1984) made a midline lesion at T10 in patients with pelvic cancer pain. The location was chosen to be just above the level of entrance of primary afferent fibers from the pelvic viscera into the spinal cord. The procedure was termed a limited midline myelotomy. Eight cases done by Hirshberg, using a mechanical probe, were described further and a postmortem specimen showing the spinal cord lesion in one patient was illustrated (Figure 1(b)) in Hirshberg R. M. *et al.* (1996). The lesion interrupted the medial parts of the posterior funiculi but did not appear to intrude into the central gray matter or anterior white commissure. The results of the lesions in the eight cases were generally quite favorable, with pain relief that lasted as long as the patients survived and with little or no need for strong analgesic drugs.

The chief of neurosurgery at our institution, Dr. H. J. W. Nauta, made lesions using a technique similar to that described by Hirshberg in a series of

patients who had pain from pelvic or other cancers. The results in each case were again generally favorable and the need for strong analgesics greatly reduced. In one case, a midline myelotomy was done in a patient with inflammatory bowel disease secondary to irradiation that had successfully eradicated a cervical cancer (Nauta, H. J. W. *et al.*, 1997; 2000). The patient had severe ongoing pain, and the pain intensified during bowel movements. As a consequence of the pain, the patient had lost a substantial fraction of her body weight, and it was judged that she would not survive much more weight loss. After midline myelotomy, this patient lived for almost 5 years with no further pelvic pain (although she did experience subdiaphragmatic pain because of peritonitis). She died from complications of diabetes.

In another of the cases reported by Nauta H. J. W. *et al.* (1997; 2000), pain was reduced from 10 to 2–3 on the visual analog scale, and narcotic medication was tapered from 30 mg of intravenously administered morphine per hour preoperatively to 5 mg per hour within 5 days postoperatively. Another patient had unbearable pain from a presacral sarcoma, despite several efforts to resect the tumor. A midline myelotomy was done in the area shown in Figure 1(c). The lesion resulted in dramatic pain relief for the remainder of the patient's life. He survived the surgery by 36 months, and for most of this time he did not require narcotic medication. In general, only in some cases were even minor and transient sensory side effects observed. Pelvic cancer pain was consistently reduced following midline myelotomy, and narcotic usage could be decreased on average by 83%.

Several other groups around the world have had similar experiences with midline myelotomies (Becker, R. *et al.*, 1999; Kim, Y. S. and Kwon, S. J., 2000; Filho, O. V. *et al.*, 2001; Hu, J. S. and Li, Y. J., 2002; Hwang, S. L. *et al.*, 2004), and the results have been reviewed by Becker, R. *et al.*, (2002).

5.36.2 Basic Science Evidence Concerning Spinal Cord Pathways That Signal Visceral Pain

5.36.2.1 Spinothalamic Tract

The spinothalamic tract conveys somatic but also some visceral nociceptive information to the thalamus (Figure 2(a)). Studies in which recordings were made from antidromically activated spinothalamic tract neurons have demonstrated that many of these

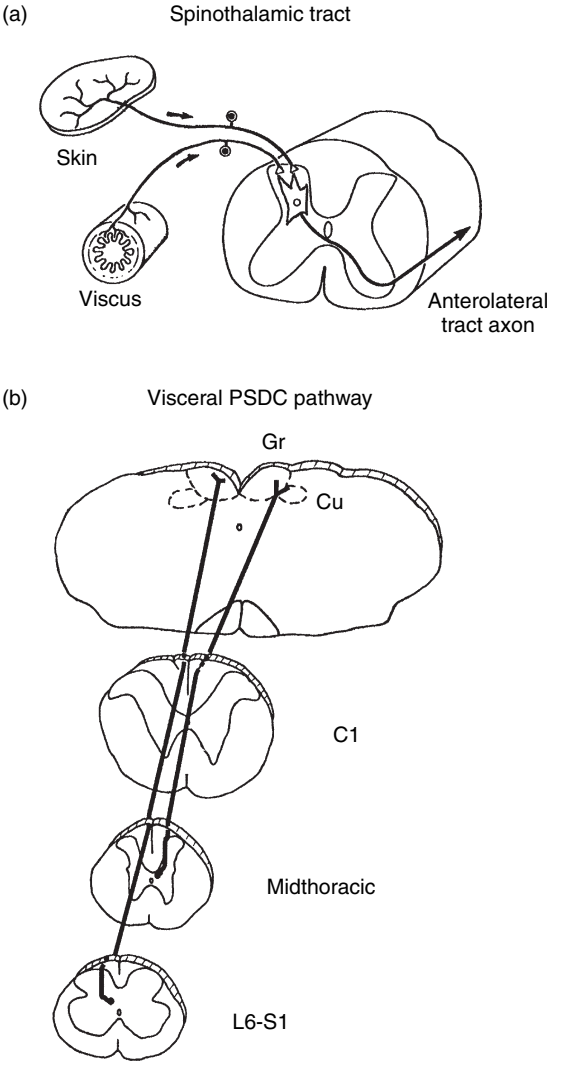

Figure 2 (a) Convergence of visceral and somatic afferent inputs on an anterolateral tract neuron. Such viscerosomatic convergence is thought to be responsible for referral of visceral pain to somatic structures. (b) Course followed by the axonal projections of postsynaptic dorsal column neurons found in the central region of the spinal cord gray matter at sacral and mid-thoracic levels. The anterograde tracer, phaseolus vulgaris leucoagglutinin (PHA-L), was injected and then several days later traced in axons of the dorsal column to the brainstem. The projection from the sacral cord ascended at the midline, whereas that from the mid-thoracic cord ascended more laterally, just ventral to the dorsal intermediate sulcus. Information about visceral nociception most likely travels with other sensory input to the thalamus in the medial lemniscus. Data from Wang, C. C., Willis, W. D., and Westlund, K. N. 1999. Ascending projections from the central, visceral processing region of the spinal cord: a PHA-L study in rats. J. Comp. Neurol. 415, 341–367; illustration from Willis, W. D., Al-Chaer, E. D., Quast M. J., and Westlund, K. N. 1999. A visceral pain pathway in the dorsal column of the spinal cord. Proc. Natl. Acad. Sci. U. S. A 96, 7675–7679.

cells can be activated (or in some instances inhibited) following stimulation of viscera. For example, Foreman and his group have shown that feline and primate spinothalamic tract cells can be excited by electrical stimulation of cardiopulmonary visceral afferent fibers, occlusion of a coronary artery, or injection of bradykinin into the coronary circulation (see review by Foreman, R. D., 1989). Similarly, spinothalamic tract cells have been shown to respond to electrical stimulation of the greater splanchnic nerve (Hancock, M. B. *et al.*, 1975; Foreman, R. D. *et al.*, 1981), distension of any of several hollow viscera, including the gall bladder (Ammons, W. S. *et al.*, 1984), kidney (Ammons, W. S., 1987), ureter (Ammons, W. S., 1989), urinary bladder (Milne, R. J. *et al.*, 1981), and colon (Al-Chaer, E. D. *et al.*, 1999) or noxious stimulation of the testicle (Milne, R. J. *et al.*, 1981). In general, spinothalamic tract and other neurons that are activated by visceral stimulation also respond to stimulation of somatic tissue. This convergence of visceral and somatic input onto spinal cord neurons, including nociceptive neurons that project to the brain, is thought to help account for the referral of visceral pain to the body wall in many clinical conditions (Figure 2(a); Head, H., 1893). Examples of the somatic receptive fields of viscero-sensitive spinothalamic cells that correspond to the distribution of pain referral are noted in Foreman (Foreman, R. D., 1989) and Milne (Milne, R. J. *et al.*, 1981). Only rarely can a spinal neuron be found that seems to respond to just visceral stimuli and not to somatic ones. However, when the search stimulus is colon distension, rather than antidromic activation from the lateral thalamus, viscerospecific responses can be recorded from cells located rostrally in the central lateral nucleus of the intralaminar complex of the thalamus (Ren, Y. *et al.*, 2006). This region has been shown to receive direct spinal innervation from lamina X neurons (Wang, C. C. *et al.*, 1999) and is rich in opiates (Sar, M. *et al.*, 1978). The spinothalamic projection from lamina X is situated at the medial-most edge of the spinothalamic tract and shifts laterally as it ascends with the spinothalamic tract.

5.36.2.2 Spinoreticular, Spinoparabrachial, Spinoamygdalar, and Spinohypothalamic Tracts

Several studies have demonstrated the effectiveness of visceral stimulation in exciting (or inhibiting) spinoreticular tract neurons (Blair, R. W. *et al.* 1984; Hobbs, S. F. *et al.*, 1990), spinoparabrachial and spinoamygdalar neurons (Menetrey, D. and De Pommery, J., 1991; Bernard, J. F. *et al.*, 1994), and spinohypothalamic tract neurons (Katter, J. T. *et al.*, 1996; Zhang, X. *et al.*, 2002). A cordotomy or a commissural myelotomy is likely to interrupt these pathways, and thus the relief of visceral pain by such lesions is likely to be at least partially explained by this, as well as by interruption of the spinothalamic tract.

5.36.2.3 Postsynaptic Dorsal Column Path

5.36.2.3.1 Historical evidence for a visceral projection in the dorsal column

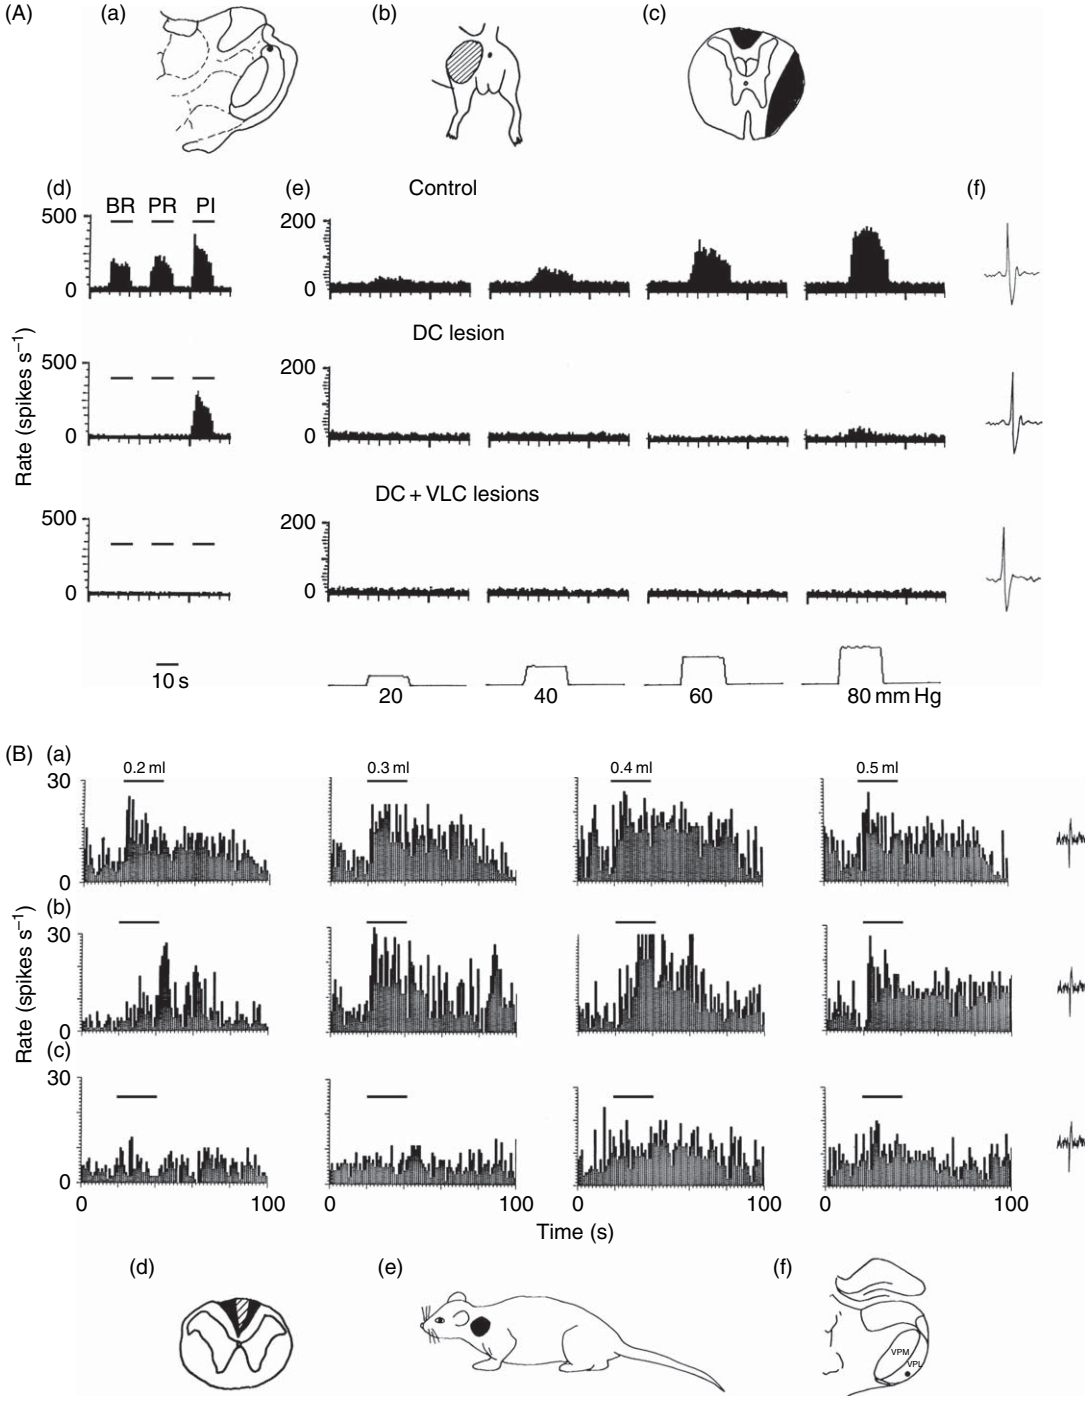
Recordings from the human posterior funiculus have revealed the presence of visceral afferents that respond to distention of the urinary bladder (Puletti, F. and Blomqvist, A. J., 1967). Responses at various levels of the dorsal column-medial lemniscus pathway have also been reported in animal experiments following electrical stimulation of visceral nerves (Amassian, V. E., 1951; Aidar, O. *et al.*, 1952; Rigamonti, D. D. and Hancock, M. B., 1974; 1978).

5.36.2.3.2 Effects of interruption of the dorsal column or a lesion of dorsal column nuclei on responses of brainstem and thalamic neurons to noxious visceral stimuli

To determine if there is a visceral nociceptive pathway in the dorsal columns of experimental animals, recordings were made from viscero-responsive neurons in the ventral posterior lateral nucleus of the thalamus in rats before and after surgical interruption of either the dorsal columns bilaterally or the ipsilateral ventrolateral column, which contains the spinothalamic and associated nociceptive pathways (Al-Chaer, E. D. *et al.*, 1996a). The dorsal column lesion reduced the responses of the thalamic neurons to colorectal distension on average by about 80% (Figure 3(Ae), cf. upper and middle rows of records). The remaining response was eliminated by the lesion of the ventrolateral quadrant of the spinal cord (Figure 3(Ae), lower row of records). Responses to weak mechanical stimuli applied to the skin were abolished by the dorsal column lesion, whereas the responses to the strongest mechanical stimuli were affected only by the ventrolateral quadrant lesion (Figure 3(Ad)). Similar effects were seen when the noxious visceral stimulus was inflammation of the colon by intraluminal injection of mustard oil (not illustrated). The mustard oil produced a progressive

increase in the background activity of the viscerosensitive thalamic neurons. A dorsal column lesion was more effective in reducing the background activity than was a ventrolateral quadrant lesion.

Neurons in the rat ventral posterior lateral thalamic nucleus could also be found that responded to distention of the duodenum (Figure 3(Ba); Feng, Y. *et al.*, 1998). In these experiments, a lesion of the dorsal column placed at the midline failed to reduce the responses (Figure 3(Bb)). However, bilateral lesions just ventral to the dorsal intermediate sulcus at an upper cervical level were effective (Figure 3(Bc)).



This shift in the location of the dorsal column lesion needed to interrupt nociceptive responses in the thalamus relates to the fact that the visceral input originated from an abdominal, rather than a pelvic organ (see Figure 2(b), discussion below, and Wang, C. C. *et al.*, 1999).

The off-midline part of the dorsal column pathway that carries visceral input from the thoracic level of the spinal cord was investigated in behavioral (see Figure 2(b) and discussion below) and electrophysiological studies after noxious chemical irritation of the pancreas (Houghton, A. K. *et al.*, 1997; 2001). Noxious stimulation of the pancreas by applications of bradykinin to its exposed surface in anesthetized rats resulted in excitation of neurons in the ventral posterior nucleus of the thalamus (Houghton, A. K. *et al.*, 2001). The mean firing rate of thalamic neurons was increased $412 \pm 120\%$ above baseline during the first 40 s after bradykinin application to the pancreas and was sustained for 3–6 min. Large dorsal column lesions effectively eliminated the increased responses of thalamic neurons to applications of bradykinin on the pancreas and baseline activity remained constant. Enhanced responses to skin pinch after pancreatic application of bradykinin dropped after a dorsal column lesion from 242% over baseline back to 100%. The effects of noxious stimulation of the pancreas with bradykinin involved a spinal synaptic relay rather than a vagal relay since thalamic activation was prevented by intrathecal administration of morphine. This action of morphine could be antagonized by naloxone.

Visceral responses can also be recorded from neurons in the ventral posterior lateral nucleus in monkeys (cf., Chandler, M. J. *et al.*, 1992; Brüggemann, J. *et al.*, 1994), as in rats. The effects of a dorsal column lesion on such responses in monkeys are consistent with those obtained in rats (Al-Chaer, E. D. *et al.*, 1998).

The thalamic responses to visceral input are relayed through the dorsal column nuclei. Visceral responses of neurons in the rat ventral posterior lateral thalamic nucleus could be reduced by small electrolytic or kainic acid lesions of the nucleus gracilis (Al-Chaer, E. D. *et al.*, 1997). Responses of cells in the nucleus gracilis have been recorded after noxious stimulation of either the colon or the pancreas (Al-Chaer, E. D. *et al.*, 1996b; 1997; Houghton, A. K. *et al.*, 2001).

5.36.2.3.3 Effects of a dorsal column lesion on behavioral responses

Changes observed in behavioral experiments were consistent with the electrophysiological findings. For example, when a rat is put into an unfamiliar plastic activity box, it moves freely around in the box until it adapts to this new environment. The movements can be tracked automatically by computer. Beams of ultraviolet light cross the plastic box, and whenever a beam is blocked by the animal, this is counted as a movement. Under normal conditions, the exploratory activity gradually decreases over about 45 min. However, if the animal experiences pain, for example, because of the presence of

Figure 3 (A) shows the effects of sequential lesions of the dorsal columns (DC) and of the ventrolateral column (VLC) on one side on the responses of a neuron in the rat ventral posterior thalamic nucleus to a graded series of mechanical and visceral stimuli. The filled circle in (a) shows the recording site; the hatched area in (b) the somatic receptive field, and the black areas on a drawing of a transverse section of the spinal cord in (c) the extent of the lesions. Responses to brushing the skin (BR), application of pressure to a fold of skin with an arterial clip (PR) and pinching the skin with a stronger arterial clip (PI) are seen in (d), before and after the lesions. The responses to colorectal distentions of 20, 40, 60, and 80 mmHg are shown in (e), before and after the lesions. The action potential of the thalamic neuron at different times during the experiment is illustrated in (f) to indicate the stability of the recording. (B) Shows the effects of lesions of the dorsal columns placed in the upper cervical spinal cord at the midline or bilaterally just ventral to the dorsal intermediate sulci on the responses of a neuron in the rat ventral posterior lateral nucleus. In (a), upper row of records, are shown the responses of the neuron to graded distensions of the duodenum. The volumes of fluid injected into a balloon at the end of a catheter inserted into the duodenum are indicated in ml. The middle row of records (b) was taken after a midline lesion was made in the dorsal columns. The lesion had no clear effect. The lower row of records (c) shows that bilateral lesions of the dorsal columns ventral to the dorsal intermediate sulci substantially reduced the responses. The action potential of the thalamic neuron at different times during the experiment is shown in (b) to indicate the stability of the recording. The midline lesion is indicated by the hatched area and the more laterally placed lesions by the black area in (d). The receptive field of the neuron is shown in (e) and the recording site in (f) (A) From Al-Chaer, E. D., Lawand, N. B., Westlund, K. N., and Willis, W. D. 1996a. Visceral nociceptive input into the ventral posterolateral nucleus of the thalamus: a new function for the dorsal column pathway. J. Neurophysiol. 76, 2661–2674. (B) From Feng, Y., Cui, M., Al-Chaer, E. D., and Willis, W. D. 1998. Epigastric antinociception by cervical dorsal column lesions in rats. Anesthesiology 89, 411–420.

allodynia or hyperalgesia, the exploratory activity decreases more rapidly.

Exploratory activity is also reduced in rats with pancreatitis (Houghton, A. K. *et al.*, 1997), and this reduction is counteracted following a lesion of the dorsal columns. Similarly, infusion of bradykinin into the common bile and pancreatic duct in rats results in a reduction in rearing behavior, and this vertical exploratory behavior is increased after a dorsal column lesion (Houghton, A. K. *et al.*, 2001). Since the pancreas is an intra-abdominal organ, rather than a pelvic organ, the dorsal column had to be interrupted bilaterally and it included the areas ventral to the dorsal intermediate sulci (see below and Wang, C. C. *et al.*, 1999).

Feng Y. *et al.* (1998) inserted a balloon into the duodenum through a catheter. Distention of the balloon resulted in contractions of the abdominal muscles that were graded in force depending on the amount of balloon distention. Interruption of the dorsal columns resulted in a reduction in these abdominal muscle contractions.

The role of the dorsal column versus that of the spinothalamic tract and associated pathways was tested by Palecek J. *et al.* (2002). Exploratory activity of rats was shown to be reduced following either an intradermal injection of capsaicin (Figure 4(a)) or by inflammation of the colon with mustard oil, coupled with a mild degree of colorectal distention (Figure 4(c)). The effects of a capsaicin injection on exploratory activity could be reversed by dorsal rhizotomies on the side of the injection or by a lesion of the ventrolateral column of the spinal cord on the side opposite to the injection, but not by a bilateral lesion of the dorsal column (Figure 4(b)). By contrast, the effects of colon inflammation and distention on exploratory activity were eliminated by a bilateral lesion of the dorsal columns, and this change persisted for at least 90 days (Figure 4(d)).

5.36.2.3.4 Effects of a dorsal column lesion on the regional cerebral blood flow changes that result from colorectal distention in monkeys

In each of four monkeys anesthetized with isoflurane, it was possible to survey the changes in regional cerebral blood flow that were produced by colorectal distention, using a 4.7 T magnet for functional magnetic resonance imaging (Willis, W. D. *et al.*, 1999). The images were averaged over a standard period of time with or without visceral distention. The intensity of the colorectal distention was to 80 mm of Hg, well into the noxious range. Images through a coronal section of the brain at the level of the posterior thalamus were compared, before and after surgery (Figure 5). In one animal, sham surgery was done over the dorsal column, but no lesion was made (Figure 5, left-most images). In the other three animals, the dorsal columns were interrupted at a mid-thoracic level. At various times after recovery from the surgery, the animals were re-anesthetized and fMRIs repeated at several intervals up to 4 months after the surgery. The sham surgery had no obvious effect on the regional cerebral blood flow produced by noxious colorectal distention. However, the lesion of the dorsal columns completely eliminated the blood flow changes in all three animals, and this effect of the lesion persisted for as long as the animals were followed (Figure 5).

5.36.2.3.5 Blockade of synaptic relay in sacral cord by morphine or 6-cyano-7-nitroquinoxaline-2,3-dione

The experiments described above indicate that the dorsal columns contain axons that signal visceral pain. However, a lesion of the dorsal columns interrupts not only the ascending branches of dorsal root ganglion cells that project to the dorsal column nuclei but also axons belonging to the postsynaptic dorsal column pathway (reviewed in Willis, W. D. and Coggeshall, R. E, 2004). An experiment was therefore designed to determine if noxious visceral signals are conveyed by the direct dorsal column projection or by postsynaptic dorsal column neurons (Al-Chaer, E. D. *et al.*, 1996b). The experimental arrangement is shown in Figure 6.

Recordings were made from the nucleus gracilis, rather than from the thalamus, to avoid the complication of visceral signals conveyed by the spinothalamic and accompanying pathways, as well as by the dorsal columns. The visceral stimulus was graded colorectal distention. The location of the part of the spinal cord that relayed the information to the medulla was restricted to the sacral segments by transecting the hypogastric nerves bilaterally. A microdialysis fiber was inserted across the sacral cord in order to introduce drugs into the dorsal horn that could block synaptic transmission but that would not interfere with direct nerve impulse transmission. The drugs included morphine and the non-*N*-methyl-D-aspartic acid (NMDA) glutamate receptor antagonist, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX). The prediction was that these drugs would prevent the responses of neurons of the gracile nucleus to

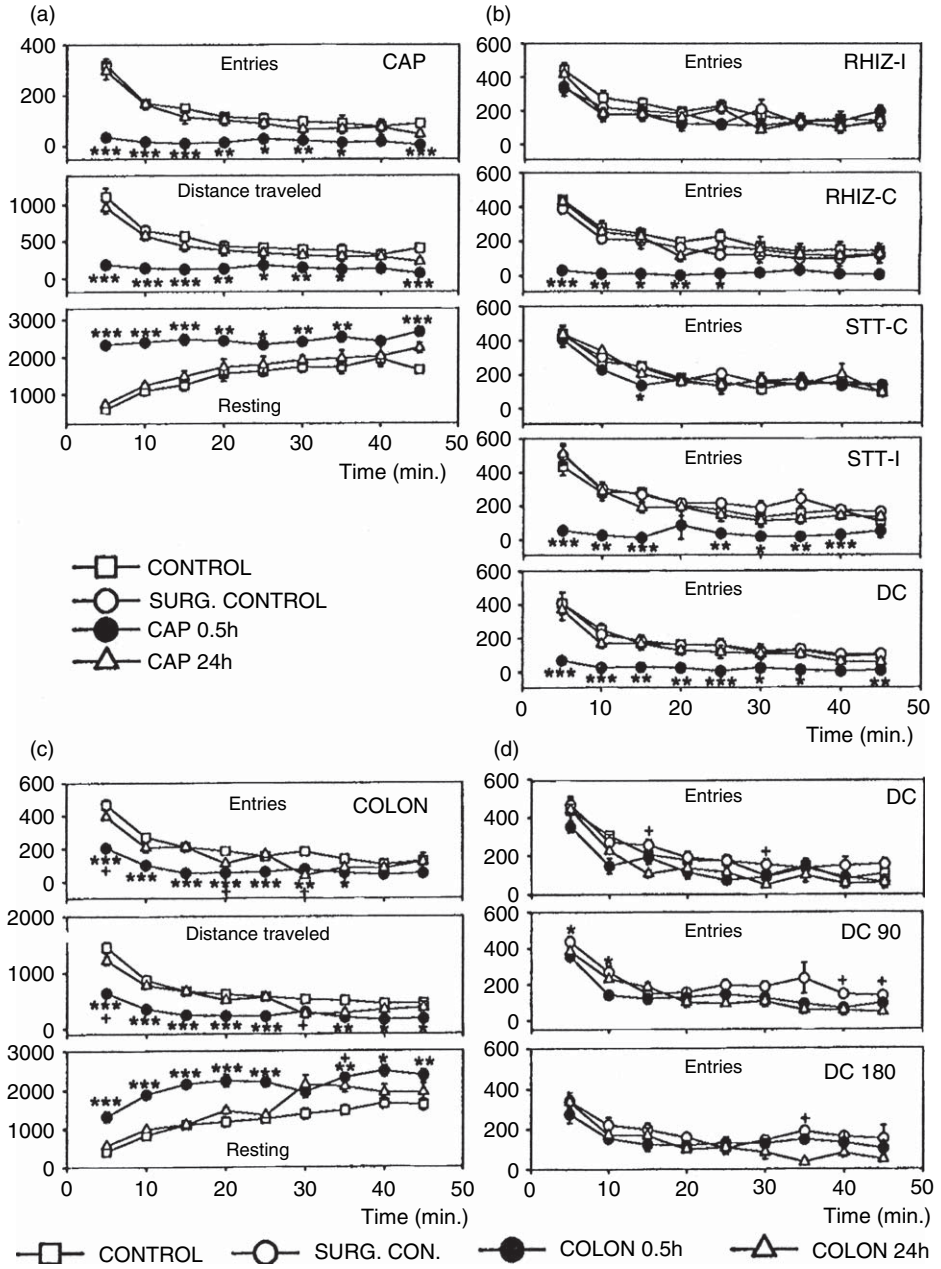


Figure 4 Time course of exploratory activity as monitored by a computer after introduction of rats into an activity box. The level of exploratory activity is determined by the number of interruptions of infrared light beams over a period of 45 min after the rat was placed in the activity box. The parameters included number of entries into a different zone, total distance traveled, and resting time. In (a) and (b), an intradermal injection of capsaicin was given, whereas in (c) and (d) mustard oil was injected into the colon and a latex balloon inserted and inflated to a pressure of 30 mmHg. At 30 min following either stimulus, exploratory activity was tested. Note that in (a), the capsaicin (CAP) injection resulted in a significant reduction in exploratory activity (and increased resting time). In (b), this was prevented by a prior extensive dorsal rhizotomy on the side ipsilateral to the injection (RHIZ-I), but was unaffected by a contralateral dorsal rhizotomy (RHIZ-C). A lesion that interrupted the spinothalamic tract contralateral to the injection (STT-C) also eliminated the reduction in exploratory activity following CAP, whereas an ipsilateral cordotomy (STT-I) had no effect; nor did a bilateral dorsal column (DC) lesion. In (c), colon inflammation and distention reduced the exploratory activity, and in (d) this change was eliminated by a dorsal column (DC) lesion. The effect lasted for 90 (DC 90) and 180 (DC 180) days. From Palecek, J., Paleckova, V., and Willis, W. D. 2002. The roles of pathways in the spinal cord lateral and dorsal funiculi in signaling nociceptive somatic and visceral stimuli in rats. Pain 96, 297–307.

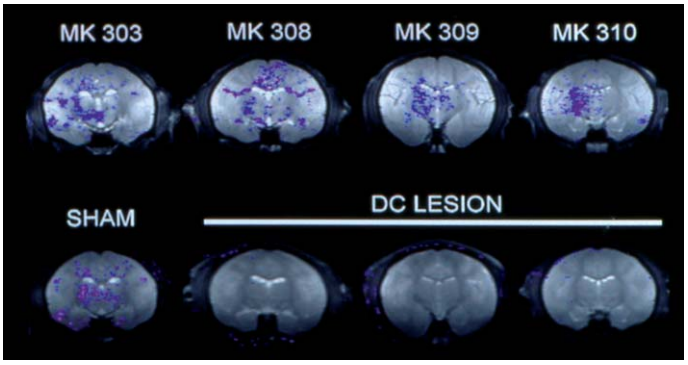

Figure 5 Functional magnetic resonance imaging showing the changes in regional cerebral blood flow in the brains of four different monkeys in coronal slices made at the level of the posterior thalamus. The blood flow changes were evoked by repeated colorectal distention to 80 mmHg under isoflurane anesthesia. The images in the upper row were made prior to surgery. Those in the lower row were from the same animals but after surgery. The animal whose images are shown at the left was subjected to sham surgery: the dorsal column was exposed at a mid-thoracic level, but no lesion was made. In the other three animals, the dorsal columns were interrupted at a mid-thoracic level. There was no obvious difference in regional blood flow changes in the animal with sham surgery, but the blood flow changes in the other animals were completely eliminated (previously unpublished data.).

colorectal distention if postsynaptic dorsal column neurons were responsible for the responses, but not if the direct dorsal column pathway were involved. This was important, since it was conceivable that noxious visceral signals could be transmitted to the dorsal column nuclei by unmyelinated, peptidergic branches of dorsal root ganglion neurons. Such fibers have been demonstrated, although the functions of these axons are still unknown (see Willis, W. D. and Coggeshall, R. E., 2004). The results of this experiment indicated that the postsynaptic dorsal column pathway is responsible for the visceral pain signals that ascend in the dorsal columns. Both morphine and CNQX blocked visceral nociceptive transmission from the colon to the gracile nucleus, and the effects of morphine were reversed by naloxone, indicating that the morphine acted on opiate receptors (Figure 7). The CNQX must have exerted its effect by blocking a critical synaptic relay that involves non-NMDA glutamate receptors.

5.36.2.3.6 Projections of the postsynaptic dorsal column pathway

The course of the ascending axons of postsynaptic dorsal column neurons in the sacral spinal cord was traced using the *Phaseolus vulgaris leukoagglutinin* (PHA-L) anterograde tracing technique and compared with the projections from postsynaptic dorsal column neurons in the mid-thoracic spinal cord (Wang, C. C. *et al.*, 1999). Injections of PHA-L were made into the central region of the spinal cord for several reasons. This area is known to receive visceral afferent input (Honda, C. N., 1985; Sugiura, Y. *et al.*, 1989), and recordings had been made in this region from a number of postsynaptic dorsal column neurons that responded to noxious visceral stimuli (Al Chaer, E. D. *et al.*, 1996a; 1996b). Many cells around the central canal have ascending projections in the dorsal columns that are labeled following injections of retrograde tracer into the dorsal column nuclei or the dorsal column itself (Hirshberg, R. M. *et al.*, 1996). The nociceptive visceral information is likely to be relayed from the dorsal column nuclei to the lateral thalamus by way of the medial lemnsicus.

However, recent observations indicate that many postsynaptic dorsal column neurons that are activated by noxious visceral stimuli are also located in the nucleus proprius of the spinal cord dorsal horn (Palecek, J. *et al.*, 2003b), presumably adjacent to postsynaptic dorsal column neurons that lack visceral input (Figure 8).

Postsynaptic dorsal column neurons in lamina X of the sacral cord were found to project their axons through the medial part of the fasciculi gracilis to the nuclei gracilis (Figure 2(b); Wang, C. C. *et al.*, 1999). Thus, the projections of these postsynaptic dorsal column cells are in exactly the position in the medial posterior columns that was targeted by the Hitchcock procedure (Hitchcock, E. 1970; 1974; 1977) and by limited midline myelotomy (see Hirshberg, R. M. *et al.*, 1996; Nauta, H. J. W. *et al.*, 1997; 2000). These axons would also be interrupted by a commissural myelotomy. However, axons that

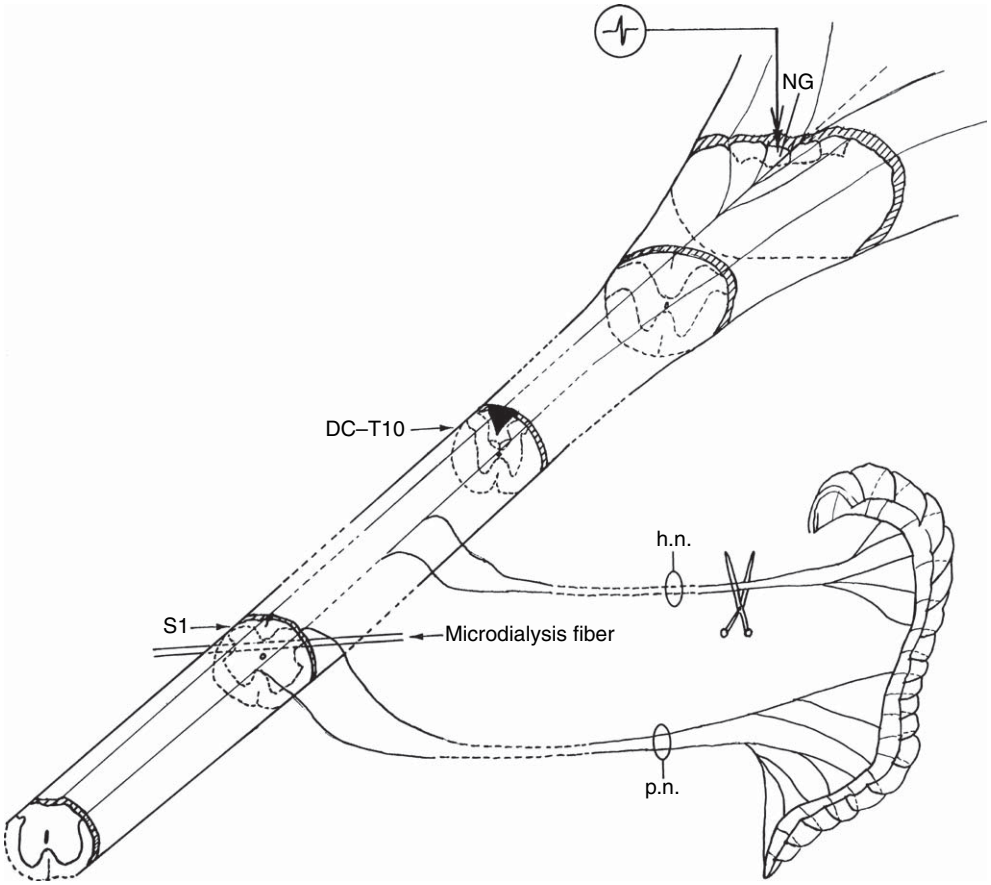

Figure 6 Drawing of the experimental arrangement. Recordings were made of the responses of neurons in the nucleus gracilis (NG, upper right) in response to colorectal distension. This avoided the problem that would have been encountered with thalamic recordings, since neurons of the ventral posterior lateral nucleus could be affected by either the dorsal column pathway or the spinothalamic tract. The input from the colon to the spinal cord was limited to just that traversing the pelvic nerve and ending in the sacral spinal cord. This was done by sectioning the hypogastric nerves prior to the experiment. A microdialysis fiber was placed across the spinal cord at S1 so that drugs that are likely to block synaptic transmission in the dorsal horn could be administered locally. Access to the dorsal column (DC) at T10 permitted a test of the effect of a dorsal column lesion. From Al-Chaer, E. D., Lawand, N. B., Westlund, K. N., and Willis, W. D. 1996a. Visceral nociceptive input into the ventral posterolateral nucleus of the thalamus: a new function for the dorsal column pathway. J. Neurophysiol. 76, 2661–2674.

ascend from postsynaptic dorsal column neurons in the mid-thoracic cord to the lateral part of the gracilis nucleus and the medial part of the cuneate nucleus do so near the dorsal intermediate septum (Figure 2(b); Wang, C. C. *et al*., 1999). Thus, there appears to be a viscerotopic organization of this visceral pathway similar to that of the somatosensory part of the postsynaptic dorsal column pathway (see Willis, W. D. and Coggeshall, R. E., 2004). The results of the studies of stimulation of internal organs of the abdomen described above by Houghton A. K. *et al.* (1997; 2001) and Feng Y. *et al.*(1998) are consistent with this observation. In these studies, distention or chemical irritation of abdominal viscera was used to activate neurons in the rat ventral posterior lateral nucleus. Lesions placed in the dorsal column at the midline failed to influence the responses. However, lesions lateral to the midline in the area of the dorsal intermediate septum were effective. Clinical studies from a group in Korea (Kim, Y. S. and Kwon, S. J., 2000) report favorable results in patients experiencing stomach cancer pain when lesions were made near the incoming thoracic dorsal root fibers rather than at the midline. This indicates that the viscerotopic organization is similar in humans and animals and that off-midline myelotomies will offer better relief of thoracic or upper abdominal visceral pain than do midline myelotomies.

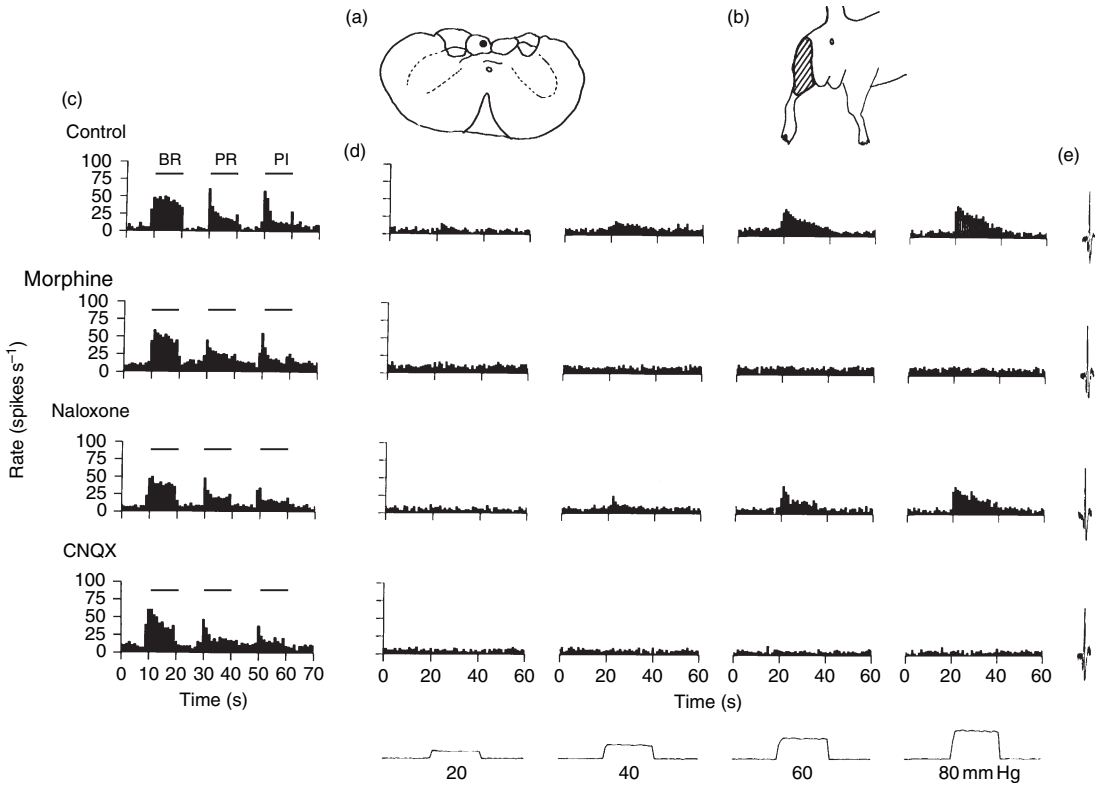

Figure 7 Effects of morphine and CNQX administered into the sacral cord by microdialysis on the responses of a neuron in the gracile nucleus to graded somatic and visceral stimuli. (a) Shows the recording site in the gracile nucleus. (b) Indicates the receptive field of the gracile neuron. In (c) are the responses of the gracile neuron to BR, PR, and PI stimuli applied to the cutaneous receptive field. (d) Shows the responses to graded colorectal distention to 20, 40, 60, and 80 mmHg. The upper row of recordings in (c) and (d) are the control responses taken before administration of drugs. The second row of recordings shows the effects of morphine given by microdialysis. There was little, if any, change in the responses to the somatic stimuli, but the responses to colorectal distention were eliminated. The third row of recordings shows that systemically administered naloxone counteracted the effects of morphine. The lowest row of recordings shows the effect of CNQX in blocking the responses to colorectal distention. In (e) are action potentials recorded at different times during the experiment to show the stability of the recordings. From Al-Chaer, E. D., Lawand, N. B., Westlund, K. N., and Willis, W. D. 1996b. Pelvic visceral input into the nucleus gracilis is largely mediated by the postsynaptic dorsal column pathway. J. Neurophysiol. 76, 2675–2690.

5.36.2.3.7 Upregulation of NK1 receptors in PSDC neurons after colon inflammation

The cells of origin of several nociceptive pathways that ascend from the spinal cord to the brain are known to contain neurokinin-1 (NK-1) receptors (Todd, A. J. *et al.*, 2000). These pathways include the spinothalamic and spinoreticular tracts. However, postsynaptic dorsal horn neurons do not contain NK-1 receptors under normal conditions, although an up-regulation of these receptors does occur in some of these neurons following visceral inflammation (Palecek, J.*et al.*, 2003a).

5.36.2.3.8 Fos expression in PSDC neurons after noxious visceral stimulation

A comparison was made of the numbers and locations of neurons belonging to the spinothalamic tract and to the postsynaptic dorsal column pathway that express Fos, the product of the immediate/early gene, c-fos, following either an intradermal injection of capsaicin or distention of the ureter (see Figure 8; Palecek, J. *et al.*, 2003b). The spinothalamic neurons were retrogradely labeled from the contralateral thalamus and the postsynaptic dorsal column neurons from the ipsilateral nucleus gracilis. Ureter distention was accomplished by tightening a ligature that had previously been placed around the ureter. The ureter was distended proximal to the site where the ligature blocked the flow of urine. Fos-labeled neurons were distributed over a considerable length of the spinal cord, from T11 to L6. This study confirmed that spinothalamic tract cells can be activated by a noxious visceral stimulus and that postsynaptic dorsal column neurons are also activated by such stimuli.

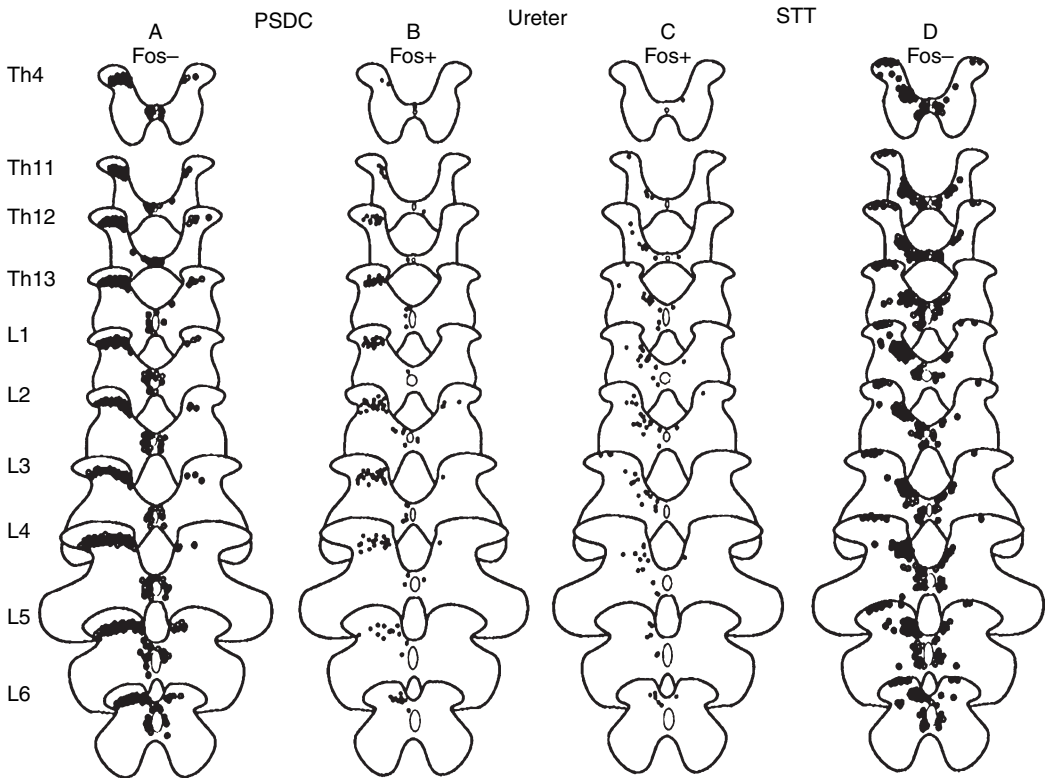

Figure 8 Effect of distention of the ureter in evoking expression of Fos protein in identified projection neurons in rats. Postsynaptic dorsal column neurons were labeled retrogradely following injection of a tracer into the nucleus gracilis (left-most column), and spinothalamic neurons were identified following injection of a different retrograde tracer into the ventral posterior lateral nucleus of the thalamus (right-most column). The middle columns show neurons identified by retrograde labeling that were also labeled for Fos protein following distention of the ureter. From Palecek, J., Paleckova, V., and Willis, W. D. 2003b. Fos expression in spinothalamic and postsynaptic dorsal column neurons following noxious visceral and cutaneous stimuli. Pain 104, 249–257.

5.36.3 Descending Facilitation

It has been shown that the responses of spinal cord neurons to visceral stimulation depend in large part on a spino-bulbo-spinal circuit (Cervero, F. and Wolstencroft, J. H., 1984; Tattersall, J. E. *et al.*, 1986; Zhuo, M. and Gebhart, G. F., 2002) that when activated facilitates visceral responses at the spinal cord level. Our anterograde tract tracing studies of the projections from lamina X demonstrate an ascending component that joins the medial edge of the spinothalamic tract (Wang, C. C. *et al.*, 1999). This ascending pathway has terminations in the nucleus raphe magnus, rostral ventromedial medulla, and medial reticular formation. This pathway is the only reported direct input to the nucleus raphe magnus from the spinal cord and is likely to be important for the activation of brainstem facilitatory neurons with axons that descend into the spinal cord to enhance the responses of spinal cord neurons to noxious visceral stimuli.

Palecek J. and Willis W. D. (2003) confirmed that a dorsal column lesion did not affect visceromotor reflex responses under normal conditions (cf., Ness, T. J. and Gebhart, G. F., 1988). However, the enhanced visceromotor responses to graded colorectal distention that followed colon inflammation with mustard oil were reduced or prevented by bilateral lesions of the dorsal columns. This suggests that the visceral reflex is enhanced because of activity induced by the colon inflammation and conveyed to the brainstem by way of the dorsal column. A lesion of the ventrolateral spinal cord eliminated the visceromotor reflex, presumably by interrupting a facilitatory pathway that descends from the brainstem and/or the ascending spinothalamic projection from lamina X.

It is our working hypothesis that interruption of the postsynaptic dorsal column pathway by a lesion placed

in the dorsal columns reduces visceral pain not only because such a lesion prevents visceral pain signals from reaching the thalamus by way of the dorsal column nuclei and medial lemniscus, but also because of a reduction of descending facilitation affecting visceral nociceptive neurons in the spinal cord, including post-synaptic dorsal column and spinothalamic tract neurons.

Glossary

referred visceral pain Visceral pain is not generally felt at the source, but rather is perceived as arising from other tissues (skin and/or muscle) innervated by non-visceral nerves having input onto second-order spinal neurons that converges with input from visceral organs onto the same spinal neurons. Accordingly, visceral pain is commonly referred (or transferred, an older terminology) to non-visceral tissues.

nociceptor sensitization Sensitization of nociceptors reflects a change in their excitability expressed as an increase in response magnitude to a noxious intensity of stimulation accompanied by a reduction in threshold stimulus intensity required to activate the nociceptor.

visceral nociceptors Sensory endings in viscera which, when activated by an adequate stimulus (stretch/tension, ischemia, inflammatory mediators), commonly give rise to sensations of discomfort and pain.

visceral hypersensitivity Increased sensitivity or response to a visceral stimulus, which can arise from sensitization of visceral sensory endings (e.g., visceral mechanoreceptors), sensitization of central nervous system neurons receiving increased input from sensitized visceral sensory endings, or a combination of both. Clinically, visceral hypersensitivity is associated with discomfort or pain produced by normally non-pain-producing stimuli (e.g., ingestion of food, normal bladder fillling) and commonly includes increased sensitivity to probing in the areas of referred visceral sensation, which moreover are increased in size (area).

5.37.1 Introduction

Of all possible sources of pain within the body, pain arising from internal organs commonly generates the greatest autonomic and emotional responses. This is linked to several characteristics of visceral pain, the most apparent being that the source of pain is neither visible nor typically felt at the source. Visceral pain also is commonly diffuse in character and poorly localized. In addition, it is also referred (or transferred) to nonvisceral, somatic structures (like skin and muscle), and there is considerable overlap in areas of referred pain from adjacent organs. For example, sites of referral from thoracic and abdominal organs (esophagus, gallbladder, and heart) overlap, making it difficult for both physicians and patients to determine the source of pain. That diffuse substernal chest pain has high emotional valence is readily appreciated, given the potential significance of such pain. Similarly, pelvic genitourinary organs have overlapping patterns of referral with the distal colon. It is also characteristic of visceral pain that the areas of referred sensation increase in size and sensitivity in organ inflammation and disease. For example, repetitive episodes of angina lead to increased tenderness (hyperalgesia) of chest and shoulder skin and abdominal tenderness spreads and increases in area in interstitial cystitis and irritable bowel syndrome (IBS).

Distinct from cutaneous, muscle, or joint pain, tissue-damaging stimuli do not commonly produce pain when applied to the viscera. Tissue crushing, cutting, or burning stimuli applied to visceral tissue generally produce little conscious sensation and rarely produce pain. Instead, stretch of the smooth muscle layers of hollow organs (e.g., by distension), traction on the mesentery, ischemia, and inflammation are more reliably uncomfortable or pain-producing in viscera. The bases of the above attributes of visceral pain and unique features that distinguish visceral from nonvisceral pain are the focus of this chapter.

5.37.2 Visceral Sensation

The viscera are invested with a wide range of sensory receptors, although when activated in healthy organs they do not generally give rise to conscious sensation. This raises the issue of whether these neurons are afferent or sensory, which is considered below in Section 5.37.3. We are generally unaware of movement of air in and out of the lungs, blood flowing through vessels, beating of the heart, or food in the stomach despite the fact that sensory receptors in the bronchial tree, lungs, vessels, heart, esophagus, and stomach are activated by these events. Information from activation of visceral sensory neurons is faithfully transmitted to the central nervous system, but rarely is perceived. Rather, activation of most visceral sensory receptors plays important roles in the regulation and maintenance of many essential functions (e.g., respiration, blood flow, food digestion), which requires rapid feedback to adjust to changes in demand due to exertion, food intake or other activities. While autonomic functions associated with the visceral afferent innervation can influence affective and cognitive processes and are, in turn, influenced by affective and cognitive processes, most of the afferent input from the viscera never reaches consciousness.

Visceral events, of course, do lead to conscious sensations. Under physiological conditions, humans perceive a sense of fullness related to organs involved in food intake (i.e., stomach) or waste elimination (rectum and bladder). Aside from these sensations related to functions that trigger intentional changes in behavior, most consciously perceived input from the viscera carries negative connotations, such as nausea, palpitation, dyspnea, discomfort (e.g., overfilling, gas, bloating), and pain. Normally, visceral pain is infrequent, but in cases of functional gastrointestinal disorders (e.g., nonulcer dyspepsia, IBS (see Chapter Irritable Bowel Syndrome), noncardiac chest pain, functional abdominal pain syndrome), interstitial cystitis/painful bladder syndrome, inflammatory visceral disorders (e.g., pancreatitis, inflammatory bowel disease), neoplasias, etc., discomfort and pain are common, persistent, and typically difficult to treat.

The so-called functional visceral disorders are characterized by pain and discomfort and enhanced sensitivity to stimuli in the absence of a demonstrable organic cause (i.e., there are no apparent structural, biochemical, or inflammatory conditions to explain the symptoms). Such functional disorders constitute a significant socioeconomic burden worldwide; the estimated prevalence of abdominal pain syndromes can range widely for different specific syndromes, but prevalence rates typically range between 22% and 28% of the adult population (Halder, S. L. and Locke, G. R., 2007). Characteristically, these and other visceral disorders are characterized by hypersensitivity, meaning

that normally non-pain-producing visceral events are perceived as uncomfortable or painful, which is likely contributed to by both peripheral and central nervous system mechanisms.

5.37.2.1 Organization of Visceral Sensory Innervation

The viscera are unique among all tissues in the body. Each internal organ is innervated by two nerves, which share some functions, but are not physiologically redundant and include important functional distinctions. Anatomically, the visceral sensory innervation is physically associated with the sympathetic and parasympathetic divisions of the autonomic nervous system. Correspondingly, Langley J. N. (1921) termed visceral afferent fibers associated with sympathetic nerves afferent sympathetic fibers. This sometimes confusing nomenclature has been replaced by use of the name of the nerve (e.g., inferior cardiac, lumbar splanchnic, pelvic), which in addition avoids assigning putative function(s) to the visceral innervation. Given the physical association of the visceral innervation with the autonomic nervous system, visceral afferent fibers are thus contained in nerves that terminate in the spinal cord (spinal nerves) or in the brainstem (vagus nerves).

The bilateral vagus nerves are perhaps the most widely distributed nerves in the body. They innervate most internal organs, including all of the thoracic viscera (proximal esophagus, heart, bronchopulmonary system), most of the abdominal viscera (distal esophagus, stomach, small and proximal large intestines, liver, pancreas, etc.), and some of the pelvic viscera. The vagus nerves are mixed and contain both efferent and afferent axons, but most axons in the vagus nerves ($\geq$80%) are sensory (afferent) fibers and the remainder parasympathetic efferents. The nodose (primarily) and smaller, rostrally located jugular ganglia contain the cell bodies of vagal afferent fibers, most of which terminate bilaterally with some viscerotopic organization in the medullary brainstem nuclei of the solitary tract (NTS). Some vagal afferents, at least in nonhuman primates and rats, project to the upper cervical spinal cord (C1–2), where they may contribute to referred sensations and modulate nociceptive processing within the spinal cord (Foreman, R., 1999).

The cell bodies of spinal afferents innervating the viscera are located bilaterally in dorsal root ganglia (DRG) from the cervical to sacral spinal cord. As mentioned above, their axons travel with sympathetic efferent fibers (except for the pelvic nerves) and, thus, traverse pre- and paravertebral ganglia *en route* to the spinal cord (Figure 1). In prevertebral ganglia, some afferent axons give rise to collateral branches that synapse on intraganglionic neurons and influence organ function (e.g., motility, secretion).

5.37.2.2 Visceral Nociceptors and Sensory Endings

Because tissue-damaging crushing, cutting, or burning stimuli that generate pain from skin do not commonly produce pain when applied to the viscera, it was long argued that the viscera were not innervated, and when visceral innervation was established, it was argued that the viscera were insensate. It is now well established that stimuli adequate for activation of visceral nociceptors differ from those adequate for activation of cutaneous nociceptors. They include distension of hollow organs, traction on the mesentery, ischemia, and inflammation. For example, experimental hollow organ distension reproduces in patients the localization, intensity, and quality of sensations associated with their visceral disorder. Because distension of hollow organs, as well as traction on the mesentery, are mechanical events (stretch), it is assumed that many visceral nociceptors are mechanoreceptors with receptive endings in visceral smooth muscle layers or serosa where they transduce the mechanical energy of tension/stretch into electrical activity (nerve membrane depolarization, action potentials). There are chemo-nociceptors in epithelial and subepithelial layers of visceral organs, but they have not been studied as extensively as have mechanoreceptors and their receptive endings have not been identified as they have for some mechanoreceptors.

Virtually all visceral sensory neuron axons are slowly conducting, thinly myelinated Aδ- or unmyelinated C-fibers. Because mechanical events are common in most organs, visceral mechanosensation and endings in muscle layers of hollow organs that respond to tension/stretch have been the focus of most studies. Unfortunately, the morphology of spinal nerve peripheral terminals in organs is virtually unknown; they are assumed to be free without structural specialization. However, two morphologically distinct endings associated principally with vagal afferent endings have been described. Intraganglionic laminar endings (IGLEs), which have been shown to be mechanosensitive, and intramuscular arrays (IMAs) are located in the upper gastrointestinal tract (Zagorodnyuk, V. P. and

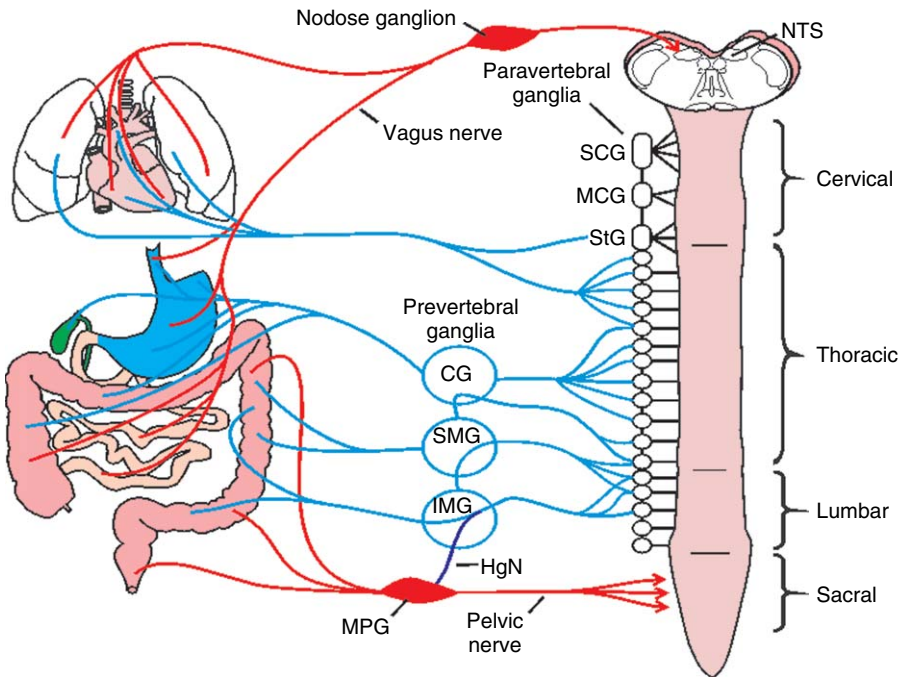

Figure 1 Cartoon illustrating innervation of the viscera. The vagus nerve innervates organs in the thoracic and abdominal cavities. Visceral afferent nerves that terminate in the spinal cord also innervate organs in the thoracic and abdominal cavities as well as those in the pelvic floor, including the genitalia (not shown). The cell bodies of vagal sensory neurons are contained in the nodose and jugular (not shown) ganglia with central terminations bilaterally in the nucleus tractus solitarii (NTS). The cell bodies of spinal visceral sensory neurons are contained in dorsal root ganglia interposed between the paravertebral ganglia (the sympathetic chain) and the spinal cord and are not illustrated in this cartoon. CG, coeliac ganglion; HgN, hypogastric nerve; IMG and SMG, inferior and superior mesenteric ganglia, respectively; MPG, major pelvic ganglion. SCG, superior cervical ganglia; MCG, middle cervical ganglia; StG, stellate cervical ganglia.

Brookes, S. J. H., 2000; Zagorodnyuk, V. P. *et al.*, 2003). As their name indicates, vagal IGLEs appear as branching endings surrounding neurons within a ganglion of the myenteric plexus (Phillips, R. J. and Powley, T. L., 2000; Powley, T. L. and Phillips, R. J., 2002). IGLEs associated with vagal afferent terminals are present throughout much of the gastrointestinal tract, but are most densely distributed in the esophagus, stomach, and duodenum (Wang, F. B. and Powley, T. L., 2000). Like IGLEs, IMAs are also thought to be mechanosensitive, but differ in morphology and distribution from IGLEs. IMAs are long arrays of terminals, typically running parallel with each other and parallel to the orientation of smooth muscle cells. They bridge between the parallel terminals within one of the muscle layers of an organ and form a lattice-like network. IMA distribution within the gastrointestinal tract is more restricted than that of IGLEs; IMAs associated with vagal afferent terminals are present in the stomach (cardia) and sphincters of the upper gastrointestinal tract and are uncommon in the intestines. Although terminal end organs have not been described for visceral spinal nerves, an IGLE-like low threshold, slowly adapting mechanoreceptor has been reported in the colonic and rectal innervation of the guinea-pig (Lynn, P. A. *et al.*, 2003).

Whether activation of either IGLEs or IMAs give rise to visceral pain is uncertain because it would appear, based on their essentially proximal and distal distribution within the gastrointestinal tract and low response threshold, that neither are particularly well suited to that function. Powley T. L. and Phillips R. J. (2002) have speculated that IGLEs detect rhythmic motor activity, which requires response to muscle/organ tension; IMAs also respond to muscle/organ stretch. However, the association of IMAs with sphincters, and because IGLEs and IMAs have heretofore been best described and characterized in association with vagal afferent endings, suggests a role for these mechanosensors in normal physiological processes (e.g., food intake, defecation) rather than nociception. Recent studies suggest that varicose branch points of spinal afferents within the serosa or deeper layers of the gastrointestinal tract

may correspond to fibers activated by high-intensity, noxious mechanical stimuli (Blackshaw, L. A. *et al.*, 2007).

5.37.2.3 Chemical Character of Visceral Sensory Neurons

During ontogeny, sensory neurons develop different phenotypes dependent on their differential sensitivity and exposure to growth factors. As mentioned above, essentially all visceral sensory neurons have unmyelinated or thinly myelinated axons. In DRG, this population of sensory neurons can be separated into two largely distinct groups based on the expression of growth factor receptors or other neurochemical markers (Molliver, D. C. *et al.*, 1997). Small-diameter peptide-containing DRG neurons express the high-affinity receptor for nerve growth factor trkA, the temperature-, proton-, and capsaicin-sensitive transient receptor potential vanilloid ion channel (TRPV)1 and the neuropeptides substance P and/or calcitonin gene-related peptide (CGRP). The second group of small-diameter DRG cells depends on glial cell line-derived neurotrophic factor (GDNF) during embryonic development, binds the plant lectin isolectin B4 (IB4) and releases neurotransmitters such as adenosine triphosphate (ATP) rather than peptides as transmitters. Immuno- histochemical studies have consistently shown that about 80% of visceral sensory neurons within the DRG are peptidergic and contain CGRP or substance P. Visceral sensory neurons in the placode-derived nodose ganglia, however, depend on different growth factors during development and show a different distribution of neurochemical markers. While the expression of neuropeptides CGRP and/or substance P is closely associated with the presence of TRPV1 channels in DRG neurons, this does not hold for nodose ganglion neurons; less than 10% express neuropeptides CGRP or substance P, whereas about 50% of nodose neurons exhibit TRPV1-like immunoreactivity.

In studies of cutaneous or muscle sensory neurons, expression of TRPV1, CGRP, or the presence of IB4 binding are often used as surrogate markers to classify neurons as nociceptive. As discussed below, 70–80% of mechanosensitive spinal afferents innervating abdominal or pelvic viscera are activated by innocuous intensities of stimulation (i.e., are low-threshold mechanosensors). Most studies of mechanosensitive vagal afferents, however, reveal an even more homogeneous response profile; high-threshold mechanosensitive fibers are rarely found. Thus, peptide expression is a poor predictor of physiological properties of visceral sensory neurons, arguing against the use of neurochemical content as a surrogate indicator of function.

Subsequent studies have established by immunohistochemistry, *in situ* hybridization, and/or current or voltage response to ligands applied directly to cell soma that some visceral sensory neurons also contain other peptides (e.g., vasoactive intestinal polypeptide, cholecystokinin) and express ligand-gated channels and receptors (e.g., different members of the family of transient receptor potential channels, including TRPV1, acid-sensing ion channels (ASICs), both ionotropic and metabotropic glutamate, purinergic, serotoninergic, γ-aminobutyric acid (GABA)-ergic, and opioid receptors). As information continues to accumulate, it is apparent that there is no marker at present that distinguishes visceral sensory neurons from nonvisceral sensory neurons or visceral nociceptors from nonnociceptors.

It could be argued that visceral sensory neuron terminals are generally exposed to a richer chemical milieu than other sensory neurons (and thus express a wider array of receptors and channels, although this has not been quantified). The environments in which visceral sensory endings reside include exposure to acids, digestive enzymes, hormones, nutrients, toxins (ingested or secreted by gut flora, for example), metabolites of xenobiotics, and bioactive chemicals released from nearby enteric nervous system neurons, sympathetic nerve terminals, epithelial cells like enterochromaffin cells in the gut, and urothelial cells in the urinary bladder and mast cells. Visceral sensory neurons have been shown to respond to products released in these environments, including protons, norepinephrine, serotonin, histamine, tryptase, ghrelin, cholecystokinin, and other gastric and duodenal secretions that initiate digestion and motility.

In the gastrointestinal tract, serotonin plays an especially important role as a signaling molecule. More than 90% of the body's serotonin is found within the intestine with most stored in secretory granules on the basolateral side of enteroendocrine cells. These enteroendocrine cells are specialized epithelial cells that can release into the lamina propria a variety of mediators, including serotonin, upon mechanical or chemical stimulation, which secondarily activate extrinsic and intrinsic sensory neurons. Interestingly, the number of enteroendocrine cells increases after intestinal inflammation and remains

elevated in patients with continuing complaints despite resolution of the inciting infection (Spiller, R. C. *et al.*, 2000), suggesting that serotonin release from enteroendocrine cells is important in the pathogenesis of functional bowel disorders.

An example illustrating the importance of luminal factors within the gastrointestinal tract is the interaction between the PAR_2 receptor and the pancreatic enzyme trypsin, which is especially relevant under pathologic conditions. The PAR_2 receptor is a member of the proteinase-activated receptor (PAR) family, a group of G-protein-coupled receptors characterized by a tethered peptide–ligand that is part of the molecule and can activate the receptor once cleaved from the molecule by specific proteases. The pancreatic protease trypsin is one of the endogenous proteases that cleaves the ligand and thus activates the receptor. Pancreatic acinar cells secrete precursor forms of proteolytic enzymes, such as trypsin, that require activation within the lumen of the small intestine. During pancreatitis, however, activated trypsin is also present in the pancreatic duct and parenchyma. Experimental infusion of trypsin into the pancreatic duct activates pancreatic sensory neurons, most of which express PAR_2 immunoreactivity, and triggers aversive behavior in animals. Selective experimental activation of PAR_2 receptors mimics this effect, suggesting an important role of PAR_2 in pain during acute pancreatitis (Hoogerwerf, W. A. *et al.*, 2001; 2004). Similarly, mouse colon sensory neurons contain immunoreactivity for the PAR_2 receptor and PAR_2 agonists depolarize those neurons and cause a sustained hyperexcitability (Ahmed, K. *et al.*, 2007). Relevant to IBS, biopsy samples from IBS patients release greater amounts of proteases than do samples from controls (Cenac, N. *et al.*, 2007). Supernatants from colonic biopsies of IBS patients produce visceral hypersensitivity when given intracolonically in control, but not PAR_2 knockout mice. Mast cells, which are closely associated with nerves in the human gastrointestinal mucosa (Stead, R. H. *et al.*, 1989), are also a source of tryptase as well as other potential mediators and modulators of visceral sensation (Bueno, L. *et al.*, 1997; Barbara, G. *et al.*, 2006). Mucosal biopsies from IBS patients contained mediators that increased activity in rat mesenteric afferents, an effect inhibited by histamine H_1 receptor blockade and serine protease inactivation (Barbara, G. *et al.*, 2007).

In the airway system, similarly specialized cells have been identified within the epithelium of the intrapulmonary bronchial tree. Based on their ultrastructural and neurochemical characteristics with large, dense core vesicles and neuropeptide expression, they are referred to as neuroendocrine cells or neuroendocrine bodies when clustered in small groups (Cutz, E., 1982). Histological studies combining immunohistochemistry, retrograde labeling, and/or vagotomy reveal a complex innervation with vagal and spinal afferents projecting to these cells or cell clusters, where nerve terminals branch with formation of varicosities at branch points (Adriaensen, D. I. *et al.*, 2003). Neuroepithelial bodies likely function as oxygen sensors within the airways as hypoxia inhibits potassium currents (Fu, X. W. *et al.*, 2000). However, acute allergic inflammation triggers depletion of peptides from airway neuroepithelial cells, suggesting a role in broader signaling under physiologic and pathophysiologic conditions (Dakhama, A. *et al.*, 2002).

While the expression of one or another receptor or ligand-gated channel of a particular subunit composition may be determined at some future time to identify all or a subset of visceral sensory neurons, one feature of visceral sensory neurons may distinguish them from nonvisceral counterparts, and that is cell size. Cutaneous nociceptors are on the whole associated with thinly myelinated and unmyelinated axons and it is generally the case that these nociceptors have small-diameter cell bodies (e.g., $\leq$15–20 μm). Virtually all visceral sensory neurons have thinly myelinated or unmyelinated axons, yet their cell bodies tend to be medium in size (e.g., $\geq$25 μm in diameter), at least those associated with the gastrointestinal tract and urinary bladder. This is of importance when nociceptors are studied and identified principally on the basis of cell diameter because visceral nociceptors are not generally contained in the population of small-diameter sensory neurons assumed to be nociceptors solely because of small diameter.

The foregoing addresses, at least indirectly, identification of and assignment of function of sensory neurons, including visceral sensory neurons, based on different properties of the cells: size (diameter), cell content (e.g., peptides), expression of one or another channel or receptor, dependence on exposure during development to different growth factors. Assignment of function based upon one or more of these properties is unfortunately relatively common in the literature, and is both confusing to nondiscriminating readers and misleading. It is not possible at present to assign function (e.g., nociceptor) to a sensory neuron based on any of the above properties. As discussed

below, nociceptors, including visceral nociceptors, are defined by response to an adequate stimulus, and even then assignment of function can be difficult, if not contentious, if the quality of the stimulus is uncertain, unknown or of limited physiologic relevance, such as punctate stimulation of viscera.

5.37.2.4 Central Organization of Visceral Pain

5.37.2.4.1 Vagus nerves

Although they extensively innervate the viscera, the vagus nerves are generally considered not to play a role in nociception. However, they may contribute to the complex sensory experience of visceral pain, which includes strong autonomic reactions, including nausea or dyspnea. Vagal afferents project to the bilaterally located nuclei of the solitary tract in the dorsal medulla, an important relay station for visceral input. Vagal input reaches more rostral brain structures involved in autonomic regulation, such as the hypothalamus, supraoptic nucleus, and – via the parabrachial nucleus and ventro-medial thalamus – the insular cortex, anterior cingulate cortex, and amygdala, regions that play a role the regulation of affective responses to different stimuli including pain.

5.37.2.4.2 Spinal nerves

Because vagotomy was found to be generally ineffective in relieving visceral pain, whereas spinal nerve transaction or destruction of sympathetic prevertebral ganglia often provided pain relief (at least for a limited period of time), the spinal visceral nerves (sympathetic afferents) were inferred to be the conveyors of nociceptive information from the organs to the spinal cord. Their termination in the spinal cord is noteworthy on several counts. Firstly, spinal visceral afferent fibers terminate in a pattern that largely overlaps with terminations of cutaneous nociceptors: superficial layers of the spinal dorsal horn, deeper in lamina V and dorsal to the central canal, an area often referred to as lamina X. Visceral afferent fibers also terminate within the interomediolateral cell column/sacral parasympathetic nucleus where afferent input influences efferent output back to the same as well as to other organs (Figure 2). Secondly, spinal visceral afferents represent less than 10%, and probably closer to 5%, of the total afferent input into the spinal cord from all tissues. In compensation for this relatively sparse input, the central projection of a single visceral afferent fiber bifurcates at its spinal segment of entry in the dorsal root into caudally and rostrally directed main branches that can extend in either the dorsal funiculus or Lissauer's tract for two or three spinal segments before penetrating the spinal dorsal horn. In addition, during their longitudinal journey these main branches give off multiple collateral branches into the spinal dorsal horn (superficial laminae and laminae V and X, including contralateral laminae V and X) where, moreover, their number of terminal swellings are greater than found on cutaneous C-fiber

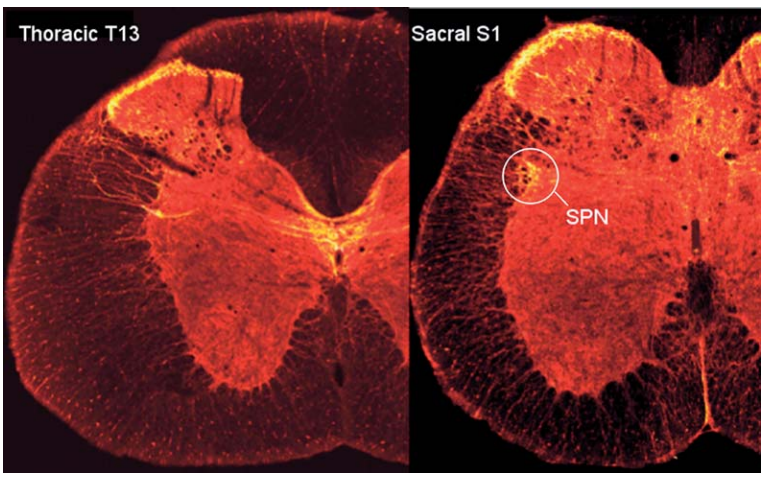

Figure 2 Distribution of visceral afferent terminals in the thoracic and sacral spinal cord. Photomicrographs illustrate internalization of the substance P receptor (yellow) in the superficial dorsal horn and area dorsal to the central canal in rat T13 and S1 spinal cord sections. Internalization of the substance P receptor was produced by distension of the colon in the rat (Honoré, P., Kamp, E. H., Rogers, S. D., Gebhart, G. F., and Mantyh, P. W. 2002. Activation of lamina I spinal cord neurons that express the substance p receptor in visceral nociception and hyperalgesia. J. Pain 3, 3–11). SPN, sacral parasympathetic nucleus.

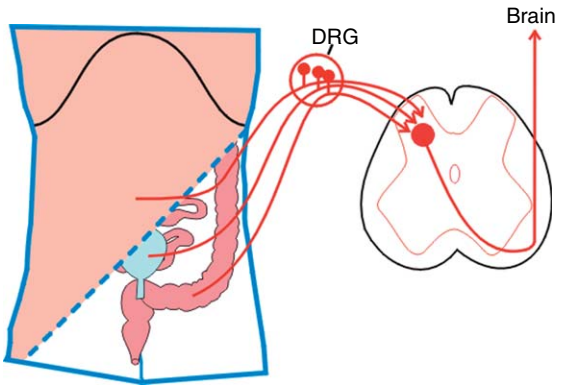

Figure 3 Illustration of viscerosomatic and visceroviscerel convergence of inputs onto a second-order spinal neuron. Illustrated is input from the abdominal skin, urinary bladder, and distal colon onto the same spinal neuron. Activation of the second-order neuron is illustrated here as being conveyed to the brain via the anterolateral ascending pathway; not illustrated is a postsynaptic dorsal column pathway, which also conveys visceral sensory information to the brain. DRG, dorsal root ganglion.

terminations within the spinal dorsal horn (which are typically limited to the spinal segment of entry). These anatomic characteristics of visceral afferent spinal terminations surely contribute to the diffuse nature of visceral pain and difficulty in localizing its source.

A final notable and defining characteristic of spinal visceral input that also contributes to poor localization is convergence. It is a feature of virtually all second-order spinal neurons upon which visceral afferent fibers terminate that convergent inputs from somatic and/or other visceral organs are also received. Typically, a single dorsal horn neuron that receives a visceral input (e.g., from colon) has a convergent cutaneous receptive field and also receives input from another viscus (e.g., urinary bladder, uterus) (Figure 3). Thus, viscerosomatic and visceroviscerel convergence upon second-order spinal neurons is the general rule (rather than the exception), and further compromises localization of visceral inputs.

5.37.2.4.3 Spinal pathways and supraspinal terminations

Spinal visceral afferent input is further transmitted rostrally and distributed widely in the brainstem (largely associated with reflex functions; e.g., micturition), hypothalamus, and thalamus and then to areas of the cerebral cortex where discriminative and affective components of visceral information assumes consciousness and triggers responses/behavior. Interestingly, thalamic and cortical neurons that receive a visceral input also exhibit viscerosomatic and visceroviscerel convergence (e.g., Apkarian, A. *et al.*, 1995) (Figure 4). The ascending pathways in spinal cord white matter that convey visceral information to the brain are contained principally in the anterolateral quadrants of the spinal cord and in the dorsal columns. Thus, there are spinomedullary, spinopontine, spinomesencephalic, spinohypothalamic, and spinothalamic tracts that ascend in the anterolateral quadrant of the spinal cord, predominantly contralateral to the side of input. The postsynaptic dorsal column paths are ipsilateral to the side of input and ascend to the nuclei gracilis and cuneatus in the medulla, where they cross and ascend to the contralateral ventrobasal thalamus (e.g., Palecek, J. *et al.*, 2002). In addition to these principal pathways that convey information to supraspinal sites, there are intraspinal propriospinal pathways that are less well understood and presumably have modulatory functions and another pathway from lamina I neurons to pontine parabrachial nuclei and thence to the amygdala, principally the central nucleus. This latter pathway is believed to specifically convey visceral information of a noxious character to the amygdala, which importantly is associated with anxiety and affective dimensions of pain (Phelps, E. A. and LeDoux, J, E., 2005).

Functional imaging studies have complemented and expanded our appreciation of the central representation of visceral inputs. Although the current spatial resolution of imaging methods has limited ability to study the initial processing of visceral input in the brainstem, reports to date suggest that cutaneous and visceral stimuli activate similar brain regions. Pain-induced anxiety, which tends to be more significant during visceral stimulation, is associated with stronger activation of the midbrain periaqueductal gray (PAG) (Dunckley, P. *et al.*, 2005). Similarly, activation of cortical structures does not show a pattern during visceral pain distinct from somatic pain, with the anterior cingulate cortex (ACC), the anterior insular cortex and – less consistently – the primary and secondary sensory cortices activated by both visceral and somatic pain (Hobson, A. R. and Aziz, Q., 2004). Despite the overall similarity between brain patterns of activation produced by cutaneous and visceral stimuli, subtle differences have emerged. Compared to noxious cutaneous stimulation, visceral pain tends to cause a stronger activation of the ACC and typically activates the

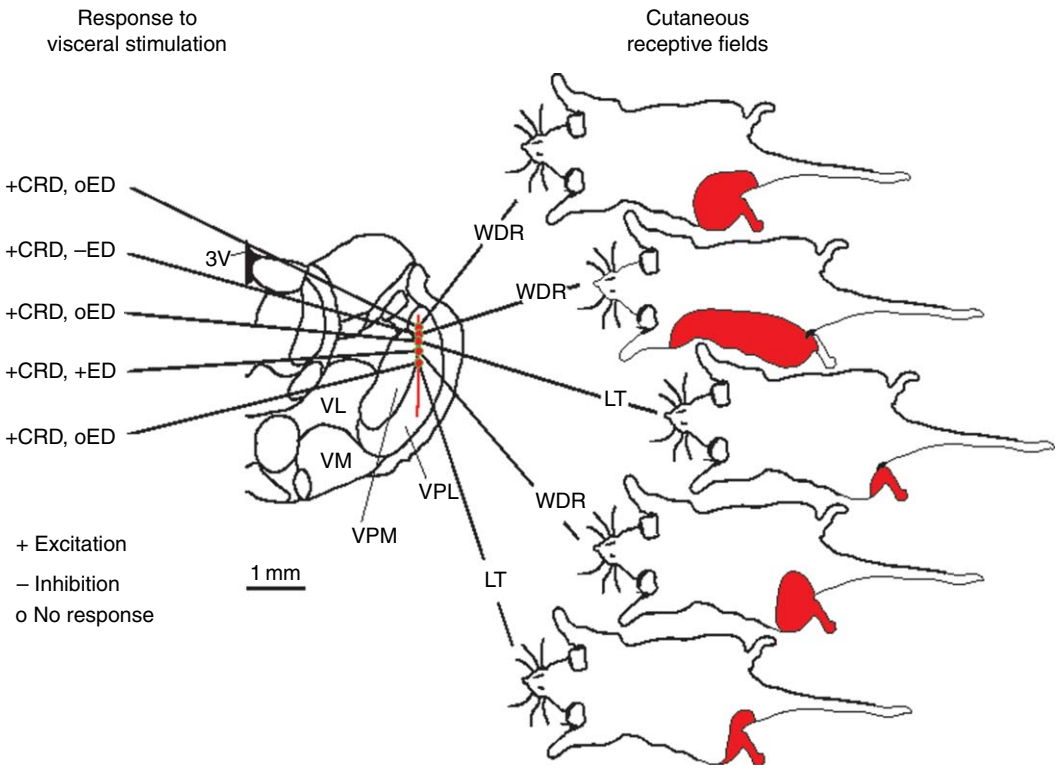

Figure 4 Illustration of viscerosomatic and viscerovisceral convergence onto neurons recorded in the rat thalamus. The vertical tract recording electrode through the ventral posteriolateral (VPL) thalamus illustrates, from top to bottom, cutaneous receptive fields on the right for five sequential thalamic neurons and responses of the same neurons to colorectal distension (CRD) and esophageal distension (ED) on the left. All neurons studied responded to both CRD and either innocuous cutaneous stimulation (identified as low threshold, LT) or both innocuous and noxious cutaneous stimulation (identified as wide dynamic range, WDR). Some neurons were also inhibited, excited or did not respond to ED. From Danzebrink R. M. and Gebhart G. F. (unpublished).

perigenual portion of the ACC, which has been linked to the generally stronger emotional reactions associated with visceral pain (Strigo, I. A. *et al.*, 2003). Interestingly, only the intensity and not the pattern of activation differs between perceived and unperceived (subliminal) visceral stimulus intensities (Sidhu, H. *et al.*, 2004).

5.37.3 Functional Basis of Visceral Pain

Nociceptors are defined by response to a noxious stimulus and their ability to encode suprathreshold stimulus intensities. Sherrington C. S. (1906) defined noxious stimuli as those that damage or threaten damage to skin, and this definition, which has been applied widely to all tissues, is problematic with respect to the viscera because tissue-damaging visceral insult is not reliably pain-producing. Instead, visceral stimuli that reliably generate sensations of discomfort or pain include, as stated previously, hollow organ overdistension, traction on the mesentery, organ ischemia, and organ inflammation, the latter two perhaps acting indirectly to alter the chemical milieu at an afferent receptive ending to increase neuron excitability to other stimuli. Accordingly, tension/stretch (produced by muscle contraction or organ distension, respectively) is an adequate acute noxious visceral stimulus at intensities (e.g., balloon pressures) above threshold for activation of visceral mechano-nociceptors. In experimental studies with humans, verbal reports or various scaling procedures identify distending pressures that are uncomfortable or painful. Concomitant recording of contractile phenomena allows differentiation between stretch (activation of receptor in parallel with muscle cells) and tension (activation of receptors in series with muscle cells). In nonhuman animal experiments, whether the intensity of visceral stimulation is noxious has to be inferred

from autonomic responses, which generally are produced at intensities of stimulation below the noxious threshold, or animal behavior. It is also noteworthy that innervation of the viscera, relative to skin, is sparse and thus spatial summation is important to activation of visceral mechanoreceptors and the production of discomfort or pain. Thus, in nonhuman animals it is necessary to use a distending balloon of sufficient length to produce a change in behavior that can be interpreted as aversive or painful. In the absence of behavioral evidence, the quality of mechanical stimulation is unknown and often difficult to establish as relevant to activation of mechano-nociceptors and visceral pain.

5.37.3.1 Visceral Mechanoreceptors and Mechano-Nociceptors

5.37.3.1.1 Afferent fiber recordings

Obviously, the stomach and temporary storage organs like the urinary bladder and distal colon/rectum experience periodic filling (and emptying), which distends these organs, commonly without generating either discomfort or pain. Mechanosensors in these organs are sensitive to and respond to filling within the physiological range, eventually leading, for example, to an urge to evacuate the bladder or bowel. Consistent with these sensations and functions produced by organ filling, most mechanosensitive afferent fibers contained in the nerves innervating these organs have low thresholds for response. The proportion of low-threshold mechanosensitive endings in spinal nerves innervating the stomach, esophagus, and gallbladder (splanchnic nerves) and the urinary bladder, uterus, and distal colon (pelvic nerves) is 70–80%, and this has been a generally consistent finding across species (cat, chicken, ferret, guinea-pig, mouse, opossum, and rat). The remaining 20–30% of afferent fibers have high thresholds for response, typically $\geq$30 mm Hg distending pressure, which corresponds very well to colon distending pressures in rats that produce behavior leading to avoidance of the stimulus. Because high-threshold mechanoreceptors in the viscera respond only to intensities of stimulation in the noxious range and encode the intensity of suprathreshold stimuli, they fulfill requirements as nociceptors and are considered to be mechano-nociceptors that signal acute visceral pain.

Unlike low-threshold cutaneous mechanoreceptors, which when activated give rise to sensation (e.g., movement of a hair follicle, movement of a cotton wisp across the skin), low-threshold visceral mechanoreceptors when activated within the physiological range of intensities generally produce no conscious sensation, but rather contribute to autonomic regulation of organ function. It has been suggested consequently that these receptors and associated axons are not sensory, but rather afferent. However, low-threshold visceral mechanoreceptors possess the uncommon attribute of continuing to respond, if not also to encode, stimulus intensity well into the noxious range. Thus, their activation at some (high) intensity of stimulation can lead to sensations perceived as uncomfortable or painful. The afferent–sensory function of visceral nerves was appreciated by Sherrington C. S. (1900), who commented that activation of visceral nerves rarely resulted in conscious sensations (i.e., an afferent function), but when sensation was produced it was typically pain (i.e., a sensory function). In all visceral nerves studied, including gastric vagal afferent fibers, low-threshold mechanosensitive afferents, when tested with high-intensity stimuli, respond vigorously and typically at a rate (frequency) greater than their high-threshold mechano-nociceptor counterparts (Figure 5). Clearly, as stimulus intensity increases, high-threshold mechano-nociceptors are also activated and it can be argued that uncomfortable or painful sensation arises from their activation. Their contribution is undeniable in acute visceral pain, but low-threshold mechanoreceptors (like their high-threshold counterparts) also possess the ability to be sensitized (see below and Figure 5), a quality commonly associated only with nociceptors. Accordingly, it is likely that both low- and high-threshold mechanoreceptors in hollow organs contribute to sensations of discomfort and pain in functional gastrointestinal (nonulcer dyspepsia, IBS) and urinary bladder (interstitial cystitis/painful bladder syndrome) disorders as well as in ischemia, inflammation, or neoplastic diseases associated with visceral pain. Consistent with this interpretation, psychophysical experiments in human volunteers have demonstrated that pharmacologic modulation of sensory function similarly shift thresholds for nonpainful and painful sensations (Vandenberghe, J. *et al.*, 2005).

There are two additional features of low- and high-threshold mechanosensitive endings in viscera that suggest their functions are not always or easily separable. First, both respond to either or both chemical and thermal stimuli in addition to mechanical stimulation (the usual experimental search stimulus). That is, they are polymodal and virtually all mechanosensitive endings when tested have been found to respond also to a

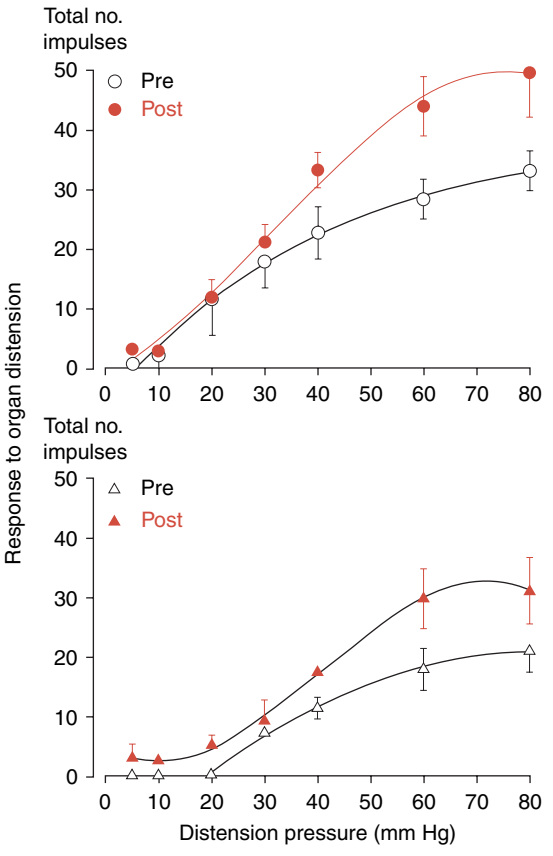

Figure 5 Stimulus–response functions for low-threshold (top) and high-threshold (bottom) mechanosensitive pelvic nerve fibers innervating the urinary bladder of the rat. Before bladder irritation, high-threshold fibers first responded at 30 mm Hg bladder distension and then encoded distending pressure throughout the range of pressures tested. In contrast, low-threshold fibers begin to respond at physiologic distending pressures, but also encoded distending pressures throughout the ranges of pressures tested. Note that response magnitude of low-threshold fibers is greater than for high-threshold fibers at all intensities of bladder distension. Note also that response magnitude increases significantly for both low- and high-threshold fibers after bladder irritation and response threshold for high-threshold fibers decreases significantly into the physiologic range (i.e., both low- and high-threshold mechanosensitive fibers sensitize). Reproduced from Su, X., Sengupta, J. N., and Gebhart, G. F. 1997. Effects of opioids on mechanosensitive pelvic nerve afferent fibers innervating the urinary bladder of the rat. J. Neurophysiol. 77, 1566–1580, used with permission from the American Physiological Society.

chemical and/or to a thermal stimulus. A considerable literature has established the sensitivity of visceral afferents in both the vagal and spinal innervations to chemical stimuli (principally hormones and putative mediators as well as nutrients that may act directly or indirectly through enteroendocrine cells). Whether such chemosensitive endings, typically studied in the mucosal surfaces of the gastrointestinal tract, are also mechano- or thermosensitive has not been systematically examined, although when examined mechanosensitivity is commonly noted. If specific and selective visceral chemosensors without mechanosensitivity exist, which is very likely the case, the argument that both low- and high-threshold polymodal mechanosensors can contribute to discomfort and pain is strengthened. Secondly, low- and high-threshold mechanoreceptors cannot be distinguished on the basis of fiber type (Aδ or C), size or content of cell soma, or pharmacologically (e.g., sensitivity to chemical or inflammatory mediators).

5.37.3.1.2 *Information acquired* in vitro

In addition to mechanoreceptor characteristics described above, in which afferent fibers were studied while distending intact hollow organs or occluding vessels, *in vitro* studies of visceral organs, typically opened and pinned flat in a dish with nerves attached, provide different information (Figure 6). For example, receptive endings in the organ can be readily localized by response to applied mechanical stimuli and the endings can be further isolated experimentally and subjected directly to chemical and thermal stimuli. Esophagus, stomach, small bowel, urinary bladder, uterus, ureter, testes, and colon–rectum all have been studied in this fashion. As above, mechanical search stimuli typically have been used and include brushing/stoking the mucosal surface of the organ to locate receptive endings functionally identified as mucosal, punctuate pressure to identify serosal receptors, and circumferential stretch of the organ to identify muscular stretch receptors. Single-fiber studies in all organs examined to date reveal typical patterns of activation, allowing inferential assignment of mucosal, muscular, and serosal receptive endings. Mucosal receptors respond only to stroking of the mucosal surface and not to stretch/tension, whereas muscular receptors respond to stretch/tension and not stroking the mucosal surface. Finally, only intense punctate stimuli activate serosal receptors. In some organs (e.g., stomach, urinary bladder, and colon) receptive endings that respond to both mucosal stroking and stretch/tension have been found (termed muscular–mucosal endings; Figure 6). It should be noted that these descriptors of receptive endings have not been histologically confirmed and are based solely on responses to mechanical stimuli. Nonetheless, use of *in vitro*

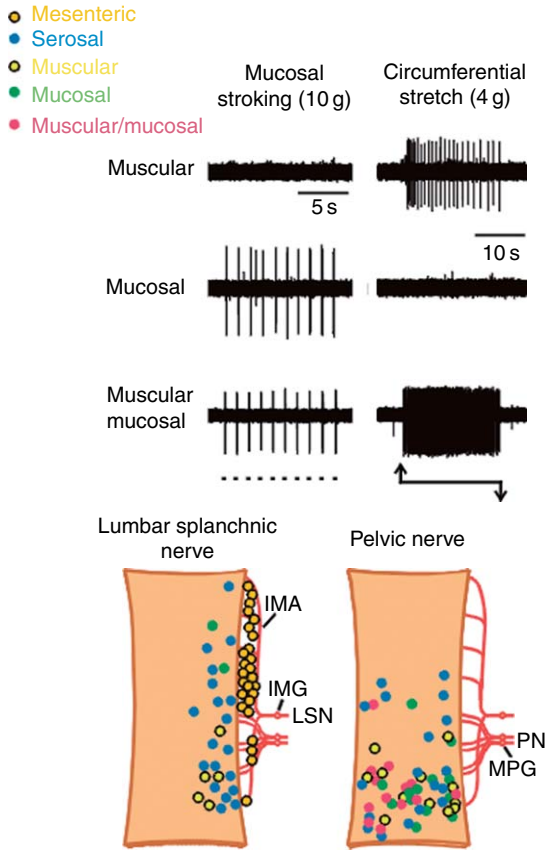

Figure 6 Responses of different types of the mechanosensitive endings innervating the mouse colon. Muscular receptors are illustrated topmost as responding to circumferential stretch of the colon but not stroking of the mucosal surface. Mucosal endings respond to mucosal stroking, but not to stretch, and muscle–mucosal fibers respond to both stroking of the mucosa and circumferential stretch. The application of strokes across the mucosal receptive ending and the duration of stretch are illustrated beneath the recordings. The distribution of receptive endings for the lumbar splanchnic nerve and pelvic nerve innervations of the mouse colon are illustrated bottommost, showing receptive endings located in the mesentery and serosa as well as those associated with muscle, mucosa and muscle-mucosa. IMA, inferior mesenteric artery; IMG, inferior mesenteric ganglion; LSN, lumbar splanchnic nerve; MPG, major pelvic ganglion; PN, pelvic nerve. Adapted from Brierley, S. M., Jones, R. C. W., III, Gebhart, G. F., and Blackshaw, L. A. 2004. Splanchnic and pelvic mechanosensory afferents signal different qualities of colonic stimuli in mice. Gastroenterology 127, 166–178.

organ–nerve preparations has confirmed many of the findings of earlier work and, importantly, has notably expanded our understanding of the contributions of mechanosensitive endings in viscera to presumed functions. For example, in addition to increasing recognition that the vagus nerves are involved in chemo-nociception (see below), there is also evidence for a role of vagal afferents in esophageal mechano-nociception (Yu, S. *et al.*, 2005). Nonnociceptive esophageal tension receptors exhibited saturable responses to esophageal distension, whereas nociceptive Aδ- and C-fiber esophageal vagal afferents discriminated noxious intensities of esophageal distension (and also responded to activators of TRPV1).

Significantly, studies of the two nerves innervating the same organ have been carried out for both the mouse colon and mouse urinary bladder. Although is has long been appreciated that the two nerves innervating an organ execute different functions, comparison of the properties of the two innervations provides new information that could, for example, inform development of therapeutic strategies. In a comparison between the lumbar splanchnic nerve and pelvic nerve innervations of the mouse colon (Brierley, S. M. *et al.*, 2004), most of the colonic receptive endings in the lumbar splanchnic nerve responded to blunt probing and were located along the mesenteric attachment and the serosa (Figure 6). In contrast, no pelvic nerve receptive endings were found in the mesenteric attachment and significantly more receptive endings responded to stretch than in the lumbar splanchnic nerve, including muscular–mucosal endings (which were not found in the lumbar splanchnic innervation). Analysis of response properties of the same receptive endings in the different innervations revealed further differences. Responses to the same intensities of stroking and stretch stimuli were significantly greater in pelvic nerve endings than in lumbar splanchnic counterparts. Overall, the pelvic nerve innervation of the mouse colon contained greater proportions of stretch/tension and mucosal receptors, which moreover generated greater magnitude responses, than the lumbar splanchnic innervation. Similarly, comparison of the lumbar splanchnic nerve and pelvic nerve innervations of the mouse urinary bladder reveals significant differences between the proportions and distribution of types of mechanosensitive receptive endings. As found for the colon, the distribution of lumbar splanchnic receptive endings in urinary bladder was more circumscribed than the distribution of pelvic nerve receptive endings, which again contained an ending (muscular–urothelial) not found in the lumbar splanchnic innervation.

A final means of study of visceral sensory neurons is to study cell soma using patch clamp methodology. These studies do not, of course, permit the type of

functional evaluation derived from single-fiber studies, and instead address aspects of mechanisms and changes in visceral neuron excitability, specifically the differential roles of voltage- or ligand-gated ion channels. Such studies have been carried out in rat stomach (vagal and splanchnic innervations), mouse intestine, mouse colon, rat colon, and rat urinary bladder (lumbar splanchnic and pelvic innervations). Because of low innervation density, the study of visceral sensory neurons requires the injection of retrograde labels into muscle layers of the organ of interest. The uptake and retrograde transport of the label into the soma allows identification of neurons projecting to the organ of interest. Consistent with results obtained *in vivo*, isolated visceral sensory neurons do not generate spontaneous activity. However, cells obtained from animals with experimentally induced inflammation show significant oscillation of the resting membrane potential, resulting in spontaneous action potential discharge, demonstrating an increase in excitability. This increase in excitability is associated with an increase in voltage-sensitive sodium currents, primarily a tetrodotoxin (TTX)-resistant sodium current, and a decrease in voltage-sensitive potassium currents, primarily the transient or A-type current (Yoshimura, N. and deGroat, W. C., 1999; Stewart, T. M. *et al.*, 2003; Dang, K. *et al.*, 2004; Beyak, M. J. and Vanner, S., 2005; Xu, G. *et al.*, 2006).

In addition to voltage-sensitive ion channels, the expression and properties of ligand-gated channels also changes in animal models of visceral pain. Ischemia is the most common cause of cardiac pain, experienced by millions of Americans suffering from coronary artery disease. Tissue acidosis due to accumulation of lactate can activate cardiac afferents and likely triggers ischemic pain. Perhaps consistent with the importance of ischemia as a trigger of visceral pain, a comparison between cardiac sensory neurons and randomly chosen neurons in the same DRG showed that a higher fraction of visceral sensory neurons express ASICs (Benson, C. J. *et al.*, 1999). Experimental injury, such as gastric ulceration, increases the current density of these acid-sensitive currents in visceral sensory neurons (Sugiura, T. *et al.*, 2005), demonstrating that sensitization does not only affect excitability (i.e., the generation of action potentials in response to a given stimulus), but also the signal transduction process (i.e., the depolarization triggered by a mechanical, chemical, or thermal stimulus). Based on the properties of proton-evoked currents, most visceral sensory neurons express different members of the ASIC family of ion channels as well as the vanilloid receptor TRPV1. The preferential expression of TRPV1 in small-diameter, presumably nociceptive neurons raised the question whether it may play a role in visceral pain. A high percentage (60–80%) of mouse and rat colon sensory neurons express TRPV1 (Robinson, D. R. *et al.*, 2004; Christianson, J. A. *et al.*, 2006) and TRPV1 is the principal detector in mouse colon of extracellular acidosis (Sugiura, T. *et al.*, 2007). Serotonin acutely alters TRPV1 function in colon sensory neurons, shifting the temperature-activation curve of this ion channel to normal body temperatures (Sugiura, T. *et al.*, 2004). About 90% of the body's serotonin is found within the gastrointestinal tract, primarily in enterochromaffin cells, and serotonin is released in high concentrations during mucosa stimulation. Studies of patients with functional bowel diseases, such as IBS, suggest changes in serotonin release and/or reuptake within the intestinal mucosa, raising the question whether modulation of TRPV1 function may contribute to the enhanced responses to physiologic stimuli seen in these patients. In addition to modulation by G-protein-coupled receptors, changes in TRPV1 expression have been examined under experimental and clinical conditions. Animal models of visceral inflammation as well as distinct human disorders from gastroesophageal reflux disease, painful bladder syndrome to rectal urgency are associated with increases in TRPV1 expression (e.g., Chan, C. L. H. *et al.*, 2003; Bhat, Y. and Bielefeldt, K., 2006; Mukerji, G. *et al.*, 2006).

Purines, which include ATP and its breakdown products, are released during cell injury and may thus play a role in nociception. Among the families of purinergic receptors, the ligand-gated P2X receptors have attracted special attention because of their role in visceral sensation. As described Chapter Urothelium as a Pain Organ, the bladder epithelium (urothelium) releases ATP during physiologic stimulation, such as stretch. Bladder sensory neurons express P2X receptors and respond to purinergic agonists (Yoshimura, N. *et al.*, 2003; Dang, K. *et al.*, 2005). Cystitis significantly increases the peak current triggered by purinergic agonists, consistent with a potential role of this signaling pathway in causing discomfort and increased micturition frequency, associated with bladder inflammation. Similarly, colon distension in the rat releases ATP in a stimulus-dependent manner, and the release of ATP is increased further after experimental induction of colon inflammation (Wynn, G. *et al.*, 2003; 2004).

Responses to colon distension in the colitis model were attenuated by a purinergic receptor antagonist, suggesting a role for ATP in colon mechanosensory transduction.

5.37.3.1.3 Gene deletions, visceral pain, and mechanosensation

The availability of mice with selected gene deletions (knockout mice) has provided the opportunity to examine the potential role of several molecules in visceral pain. To date, voltage-gated sodium channel ($Na_V1.8$), TRPV1, purinergic receptor (P2X), and ASIC knockout mice have been studied and each molecule has been found to contribute at least in part to responses to noxious visceral stimuli or of visceral mechanoreceptors. As mentioned above, the TTX-resistant sodium current is increased in neurons obtained from animals with gastrointestinal or bladder inflammation. In sensory neurons, TTX-resistant current is largely due to activation of the voltage-gated sodium channel $Na_V1.8$. Genetic deletion of this ion channel in mice is associated with a decrease in aversive behavior in response to intraperitoneal injection of acetic acid (Laird, J. M. *et al.*, 2002), supporting a potential role of $Na_V1.8$ in visceral pain. The pain behavior in this model is also likely contributed to by activation of nonvisceral afferents within the parietal peritoneum. More direct evidence was provided by other studies, one employing transient suppression of TTX-resistant sodium currents in bladder sensory neurons with antisense oligonucleotides, which abolished the increase in micturition frequency seen after acute bladder irritation (Yoshimura, N. *et al.*, 2001), and the other employing $Na_V1.8$ and $Na_V1.9$ knockout mice, which reported that neuron hyperexcitability produced by jejunitis was absent in $Na_V1.8$, but not $Na_V1.9$ knockout mice (Hillsley, K. *et al.*, 2006).

Genetic deletion of functional TRPV1 receptors also leads to changes in visceral function, suggesting a role of TRPV1 in visceral mechanosensation. TRPV1 knockout mice have a higher frequency of nonvoiding bladder contractions (Birder, A. L. *et al.*, 2001). Nerve recordings from mesenteric nerve bundles innervating the small bowel and colonic afferents within the pelvic nerve revealed blunted mechanosensation in TRPV1 knockout mice compared with wild-type controls (Rong, W. *et al.*, 2004; Jones, R. C. W. *et al.*, 2005). Deletion of TRPV1 also altered responses to inflammatory mediators, consistent with a potential role of this ion channel in peripheral sensitization (Jones, R. C. W. *et al.*, 2005). However, biophysical studies have not demonstrated a direct activation of TRPV1 by stretch. Thus, the channel likely alters cellular excitability and enhances responses to different stimulus modalities, including stretch.

As discussed separately in more detail (Chapter Urothelium as a Pain Organ), purinergic receptors play an important role in bladder function. Bladder filling triggers ATP release from urothelial cells, which activates bladder sensory neurons and may trigger reflex micturition. Consistent with this model, P2X3 knockout mice exhibit bladder hyporeflexia (Cockayne, D. A. *et al.*, 2000).

A more complex picture emerges from studies examining the role of different members of the ASIC family in visceral sensation. Genetic deletion of ASIC3 blunts responses to colorectal distension and mechanical stimulation of gastroesophageal afferents in mice, suggesting a role in visceral mechanosensation (Jones, R. C. W. *et al.*, 2005; Page, A. J. *et al.*, 2005). In contrast, deletion of ASIC1a increased mechanosensitivity of gastroesophageal and colonic afferents without affecting cutaneous afferents and deletion of ASIC2 blunted responses of gastroesophageal, but enhanced those of mesenteric afferents in the distal colon (Page, A. J. *et al.*, 2005). ASICs form heteromultimeric channels, leading to speculation that the subunit composition has significant effects on the mechanosensitive properties of visceral sensory neurons (Wemmie, J. *et al.*, 2006). Thus, genetic studies showed that – as is true for cutaneous pain – no single molecule explains the complex phenomenon of pain. Yet, some differences between cutaneous and visceral sensation has emerged, most notably the potential role of TRPV1 and P2X receptors in mechanosensation.

The foregoing studies focused on the initial events triggered by noxious visceral stimulation, namely signal transduction and cellular excitability in primary afferent neurons. Consistent with a role of substance P and neurokinin receptors in synaptic transmission of visceral afferent input within the spinal cord, genetic deletion of neurokinin receptor 1 blunted responses to intraperitoneal injection of acetic acid in mice (Laird, J. M. A. *et al.*, 2000). Despite these findings and preclinical studies with different neurokinin receptor blockers in rodent models of visceral pain, neurokinin antagonists do not appear to be effective when used to treat visceral pain in humans.

The genetic basis for visceral pain has also been addressed in humans. Considering the high

prevalence of functional gastrointestinal disorders in the general population and the expression of pain and discomfort as the primary symptoms, most studies have focused on IBS or nonulcer dyspepsia. As mentioned above, serotonin plays an important role in afferent signaling within the gastrointestinal tract. Mechanical or chemical stimuli can trigger serotonin release from enteroendocrine cells into the lamina propria, where high tissue concentrations activate terminals of both intrinsic and extrinsic primary afferent neurons within the vicinity. Reuptake of serotonin by the high-affinity transporter serotonin transporter (SERT) expressed by epithelial cells terminates this signal. This led to the hypothesis that differences in the properties of SERT may contribute to the pathogenesis of functional gastrointestinal disorders. Consistent with this assumption, deletion of SERT in mice triggers changes in bowel habits with alternating diarrhea and constipation, a common clinical manifestation in patients with IBS (Gershon, M. D. and Tack, J., 2007). Two allelic variants of the serotonin transporter have been identified in humans. These alleles have different kinetics of serotonin uptake, leading to the hypothesis that they may contribute to the pathogenesis of functional bowel disorders. While initially supported, several studies have failed to show a linkage between one of the alleles and IBS (Camilleri, M., 2004). Holtmann G. *et al.* (2004) examined the link between a G-protein β subunit and functional dyspepsia. Prior studies had shown that the expression of the two allelic forms of this molecule affected intracellular signaling in neurons and was linked to affective disorders. As was true for SERT, a subsequent study did not confirm the linkage reported in this initial observation (Andresen, V. *et al.*, 2006). These conflicting results likely reflect the fact that a complex trait, such as enhanced sensitivity to visceral stimulation, can typically not be explained by a single gene defect, but rather a complex interaction between multiple genetic and environmental factors. Thus, contributions of any single candidate gene to the variance of phenotypic expression will be limited, requiring very large studies to more conclusively address their role in the development of visceral pain syndromes.

5.37.3.2 Sleeping (Silent) Nociceptors

In the mid-1980s Schmidt and coworkers (Schmidt, R. F., 1996) characterized a novel nociceptor in the knee joint of the cat they dubbed silent or sleeping. These nociceptors could be activated by electrical stimulation, but not by the usual high-intensity mechanical stimuli tested. During the minutes and hours after experimental inflammation of the knee joint, however, these nociceptors became progressively sensitive to mechanical stimuli, including to nonnoxious movement of the joint, and developed spontaneous activity. It has subsequently been established that sleeping nociceptors do respond to mechanical stimulation in the absence of inflammation, but only at intensities that are potentially damaging to tissue, and hence they are not truly silent. Microneurographic studies suggest that between 15% and 20% of C-fiber nociceptors in human skin are of the sleeping variety (Torebjörk, H. E. *et al.*, 1996), and sleeping nociceptors also have been documented in the visceral innervation (Figure 7), although estimates of their number vary widely from ~30% to >80%. Studies of sleeping visceral nociceptors have focused principally on the pelvic nerve innervation of the rat or cat urinary bladder and colon. Whether the afferents studied were actually sleeping is uncertain, and it has to be appreciated that assignment to this category is typically based on the absence of a response to organ distension in the noxious range. Given the filling, storage, and emptying functions of the bladder and colon, which are supported by the high proportion (~70%) of pelvic nerve afferents with low thresholds for mechanical activation, that a similar large

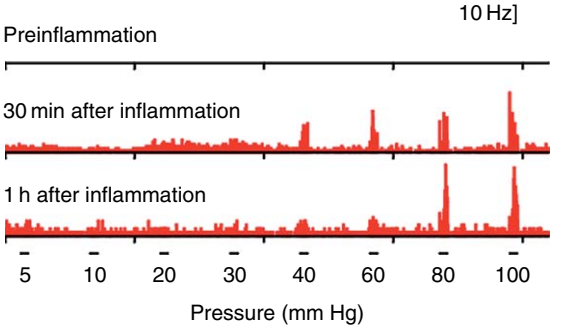

Figure 7 Illustration of a mechanically insensitive, silent (sleeping) visceral nociceptor. Responses to balloon distension of the colon (5–100 mm Hg, 20 s) are shown before experimental organ inflammation (the fiber did not respond to colon distension or bladder distension, not shown), 30 and 60 min after intracolonic instillation of zymosan. Spontaneous activity is apparent after colon inflammation as are responses to colon distension. Adapted from Coutinho, S., Su, X., Sengupta, J. N., and Gebhart, G. F. 2000. Role of Sensitized Pelvic Nerve Afferents from the Inflamed Rat Colon in The Maintenance of Visceral Hyperalgesia. In: Nervous System Plasticity and Chronic Pain, Progress in Brain Research (*eds*. J. Sandküher, B. Bromm, and G. F. Gebhart), Vol. 129, pp. 375–387. Elsevier.

proportion of pelvic nerve afferents are of the sleeping variety seems disproportionate. It is clear, however, that the proportion of sleeping nociceptors in the visceral innervation is greater than has been reported in skin, but the proportion and contributions of sleeping nociceptors to visceral pain states remains to be established. Some of these mechanically insensitive afferents may have been chemosensitive and would have responded to a chemical stimulus not tested. A potential role of chemical signaling is supported by recruitment of silent vagal gastric afferents after exposure to bile acids (Page, A. J. *et al.*, 2002).

5.37.3.3 Visceral Chemo-Nociception

Most studies of visceral afferents focus on mechanosensation, as mechanical stimuli can trigger reproducible responses without inducing tissue damage. However, visceral afferents are also exposed to potentially noxious chemical signals, such as acidity in the proximal gastrointestinal tract, and products that may accumulate during ischemia, such as lactate, protons, and bradykinin, and thus contribute to visceral discomfort and pain. Gastro-esophageal reflux disease (GERD, gastric acid reflux into the lower esophagus), myocardial ischemia, and lower airway irritation are all associated with discomfort and/or pain. Although experimental evidence obtained in animal studies is limited, both spinal and vagal afferents are involved in chemo-nociception.

Using the expression of the immediate early gene *c-fos* as a surrogate marker for neuronal activation after acid exposure of the stomach, noxious chemical stimuli activated vagal but not spinal pathways (Schuligoi, R. *et al.*, 1998). This is consistent with behavioral responses to intragastric acid administration, which were blunted after vagotomy (Lamb, K. *et al.*, 2003). In studies of mouse vagal gastro-esophageal afferent fibers, more than 50% of fibers that responded to circular tension also responded to bile acid (a component of gastric acid reflux into the esophagus); significantly, a population of mechanically insensitive (sleeping) afferents was activated by bile acid, suggesting the presence of specific chemosensors (which did to respond to other chemicals studied) (Page, A. J. *et al.*, 2002). Additional support for vagal involvement in chemo-nociception is provided by results showing that independent of the acute response to protons (glycocholic acid and hydrochloric acid), acid exposure enhanced subsequent responses of gastric vagal afferents to mechanical stimulation, suggesting a sensitizing interaction between different stimulus modalities (Kang, Y. *et al.*, 2004) (Figure 8).

Coronary artery occlusion in animals or myocardial ischemia in humans leads to the release and accumulation of a variety of substances in sinus blood (e.g., bradykinin, adenosine, serotonin, prostaglandins; see Meller, S. T. and Gebhart, G. F., 1992 for a review) that have been shown to activate cardiac afferent fibers in the spinal innervation. Experimental coronary artery occlusion also triggers a rapid decrease in myocardial pH, and both protons and lactic acid (which accumulates during tissue hypoxia) have been shown to activate ischemia-sensitive cardiac afferent fibers in the spinal splanchnic innervation (Pan, H. L. *et al.*, 1999). Many ischemia-sensitive cardiac (Pan, H. and Chen, S. R., 2002) and abdominal splanchnic afferents are also responsive to bradykinin, serotonin, and prostaglandins (see Longhurst, J. C., 1995 for review) as well as mechanical probing. As in other organs, myocardial ischemia has been reported to recruit mechanically insensitive (sleeping) cardiac splanchnic afferent fibers (Pan, H. and Chen, S. R., 2002).

In healthy subjects, the afferent innervation of the lower airways does not normally contribute to conscious sensations. However, dyspnea, chronic cough, and chronic obstructive pulmonary disease, in addition to inhalation of irritant chemicals, are associated with discomfort and/or pain, and it appears that the vagal afferent innervation plays a dominant role. As indicated previously, the cell bodies of vagal sensory fibers are contained in the nodose and smaller jugular ganglia, which are derived from placode and neural crest cells, respectively. Undem, B. J. and coworkers have provided evidence that the vagal ganglionic source of axons supplying the airways is associated with the neurochemical and physiological phenotype of the afferent fiber (Riccio, M. M. *et al.*, 1996). Nodose ganglion Aδ-fibers have low thresholds for mechanical activation, adapt rapidly to mechanical stimulation, and are not activated by capsaicin. In contrast, jugular ganglion Aδ-fibers have higher thresholds for mechanical activation, adapt slowly to mechanical stimulation, and are typically responsive to capsaicin. C-fibers associated with somata in both the nodose and jugular ganglia are also mechanically sensitive and also respond to capsaicin and bradykinin (Undem, B. J. *et al.*, 2004); in addition, C-fibers innervating the lung from the nodose ganglion express P2X receptors and respond to purinergic agonists (jugular C-fibers do not). Because proportions of these mechanically sensitive nodose and

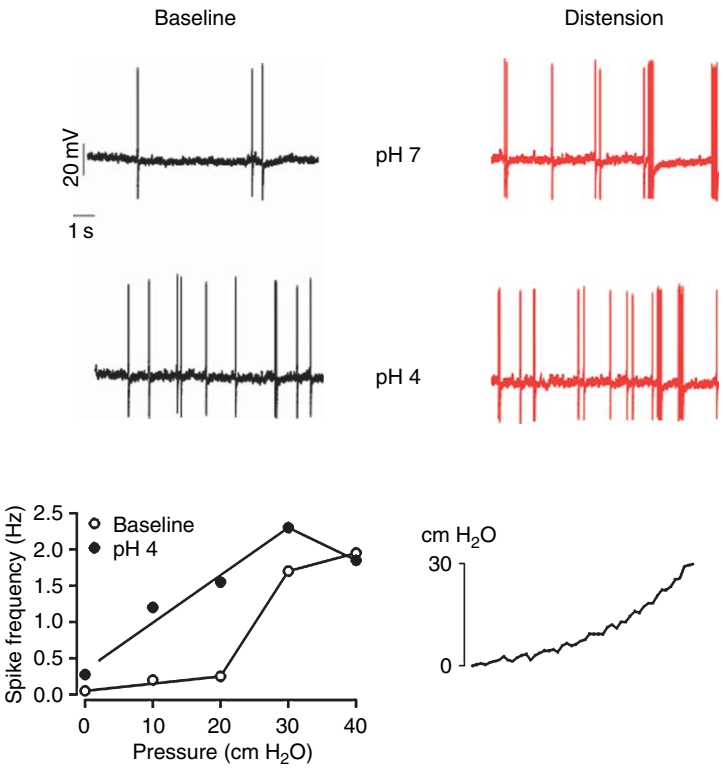

Figure 8 Intracellular recordings from a nodose ganglion neuron innervating the mouse stomach show low baseline activity (top left) and an increase (response) in activity (top right) during luminal distension (0–30 cm H_2O, 10 s, shown bottom right). When the luminal proton concentration was raised to pH 4, baseline activity and the response to distension increased. The stimulus response function for this neuron is summarized on the bottom left and demonstrates a significant shift to the left in the presence of an increase in luminal pH to 4. From Bielefeldt K. (unpublished).

jugular ganglia afferents are sensitive to acidic solutions and other algogenic chemical stimuli, they are considered to function as airway and lung nociceptors. In support, airway inflammation increases the mechanical sensitivity of the rapidly adapting population of vagal afferents and triggers an increase in the synthesis of neuropeptides substance P and CGRP (Undem, B. J. *et al.*, 2002).

5.37.4 Visceral Hypersensitivity

Like other tissues in the body, an increase in the excitability of sensory neurons innervating an organ can lead to exaggerated responses to applied stimuli, including intensities of stimulation in the physiologic range that normally do not lead to conscious sensation. Inflammation of visceral tissues, like inflammation of skin, muscle, or joints, typically increases visceral neuron excitability and raises normally unattended afferent input from the viscera to the level of consciousness in the form of discomfort and pain. By far, however, most persistent visceral pain conditions are characterized by hypersensitivity in the absence of inflammation or other cause. Accordingly, visceral hypersensitivity has been suggested to represent a biomarker for functional gastrointestinal and bladder disorders, which in the case of IBS can be experimentally established by balloon distension of the rectum. These functional disorders are relatively common, persistent, and generally inexplicable clinically. The characteristic discomfort and pain is often precipitated by ingestion of food, but also can be disassociated from events that logically would be expected to exacerbate symptoms. Typically, nonnoxious intensities of visceral stimulation (e.g., ingestion of food or beverage, low pressures of gastric or rectal distension, bladder filling) trigger painful sensations, which some have inappropriately and inaccurately termed visceral allodynia.

There is an association (~30%) between IBS and previous (and resolved) gastrointestinal infection, but antecedent or contemporaneous events that lead to development of functional disorders are otherwise unknown. Abuse in childhood, including sexual abuse, has been advanced as a contributing factor in development of functional disorders as have stress and anxiety, which are commonly reported by patients and can clearly exacerbate symptoms. Given that the cause of such disorders is unknown, there has been considerable attention paid to peripheral versus central nervous system contributions to initiation and maintenance of discomfort and pain in functional disorders. Both visceral sensory neuron excitability and sensitization and central nervous system dysregulation are considered below.

5.37.4.1 Sensitization and Excitability of Visceral Nociceptors

Sensitization is a defining characteristic of nociceptors first described by Perl for cutaneous nociceptors (see Perl, E., 1996 for an overview) and which has since been established for nociceptors innervating other tissues. Sensitization is an increase in response magnitude to suprathreshold stimuli and/or a decrease in response threshold; not uncommonly, both response magnitude increases and response threshold decreases (and spontaneous activity can develop) (see Figure 5 for examples of sensitization of responses of low- and high-threshold mechanosensitive pelvic nerve afferent fibers to bladder distension). Experimentally, sensitization is commonly produced following tissue inflammation or insult, and an extensive literature has identified mediators and mechanisms of inflammation-produced sensitization, principally in nonvisceral tissues (e.g., McMahon, S. B. *et al.*, 2006). Clinically, in functional disorders, sensitization of visceral sensory neurons is present in the absence of gross inflammation or tissue insult, but visceral sensory neurons can sensitize after exposure to noninjurious stimuli. For example, gastric vagal mechanosensitive afferents uniformly have low thresholds for response to balloon distension of the stomach, but also encode stimulus intensity into the noxious range. Response magnitude to gastric distension can be affected not only by intragastric instillation of acids or by gastric ulceration, but also by transient intragastric exposure to stimuli that do not injure the tissue (e.g., see Kang, Y. *et al.*, 2004). The significance of these findings is twofold. First, gastric vagal mechanoreceptors, which are generally considered not to contribute to visceral pain, do sensitize and significantly increase input into the central nervous system (nucleus of the solitary tract) which must have consequences, if not to interpretation or awareness of gastric sensation, then at least (or in addition) to efferent outflow to the stomach via the dorsal vagal motor nucleus. Second, that innocuous gastric stimuli can produce a time-limited sensitization of responses of gastric vagal mechanoreceptors reveals considerable neural plasticity, suggesting that normal visceral events can modulate visceral sensory neuron excitability even in healthy persons.

Because sensitization reveals an underlying change in neuron excitability, changes in neuron ion channels must be responsible for increases in response magnitude and decreases in response threshold, at least during the initial period of sensitization (see above and Gold, M. S., 2006). Experimental models of visceral hypersensitivity are associated with an increase in neuron input resistance and decrease in resting membrane potential. While the exact mechanisms have not been studied in visceral sensory neurons, changes in the expression and/or function of two pore domain potassium channels and hyperpolarization-activated I_H likely also contribute. In addition, both voltage-gated sodium (Na_V) and voltage-gated potassium (K_V) channels have been documented to change in visceral sensory neurons as predicted based on understanding of general biophysical principles. In experimental models of gastric ulceration, gastritis, ileitis, colitis, and cystitis, peak inward sodium currents significantly increase after visceral insult, and the increase is largely contributed to by the TTX-resistant component of the current (e.g., $Na_V1.8$), although precisely which sodium channel has not been established. In addition to changes in threshold, the sensitization is characterized by an increase in action potentially frequency during stimulation. Again voltage-sensitive sodium channels play an important role in this context. As already mentioned, current density increases, the voltage dependence of channel activation shifts and recovery from inactivation is accelerated, and all of these factors clearly facilitate repetitive firing. Conversely, the outward potassium current (the A type current) is reduced and the voltage dependence of activation shifts to more positive potentials in visceral sensory neurons after visceral insult, which is also consistent with an increase in neuron excitability.

5.37.4.2 Central Sensitization

In addition to increased responses and decreased response thresholds, sensitization of visceral nociceptors importantly leads to changes in excitability of central nervous system neurons upon which they terminate, a consequence termed central sensitization. Nociceptor sensitization and central sensitization are considered to underlie, respectively, the expression of primary and secondary hypersensitivity. The most readily apparent reflection of central sensitization in the clinical setting is expansion of the area of referred sensation, which is accompanied by tenderness to palpation (a reflection of peripheral sensitization). The spinal cord has been the principal focus of study with respect to central sensitization, but neurons in supraspinal sites also undergo changes in excitability and, as discussed below, supraspinal sites can contribute significantly to the maintenance of central sensitization and may play a critical role in the maintenance of chronic pain disorders, including functional visceral disorders.

The sensitization of central neurons, which has been studied extensively in the spinal cord, results from increased release of neuroactive substances (e.g., glutamate, neurokinins like substance P) from visceral sensory nerve terminals in the spinal cord and from second-order spinal interneurons upon which they may terminate. Because supraspinal sites are also engaged by persistent nociceptive input, another source of neuroactive substances (e.g., serotonin, norepinephrine, and GABA) is derived from projections to the spinal cord from the brainstem. Finally, nonneuronal glia become activated in persistent pain conditions, which has been widely documented in nonhuman animal somatic inflammatory models, and can contribute additional neuroactive substances (e.g., cytokines, chemokines) and modulators to the complex chemical milieu in spinal cord. Contributions from the latter sources (supraspinal sites and glia) likely become more important over time, and their influence may persist and contribute to altered sensations from the viscera in the absence of sustained visceral nociceptor sensitization (see below).

Changes within the spinal cord and brain stem areas of visceral input following experimental organ inflammation or noxious stimulation have been assessed by following expression of the immediate early gene, *c-fos*, upregulation of the neuronal isoform of nitric oxide synthase, and internalization of the receptor for substance P, the neurokinin 1 receptor. These experimental approaches show that organ insult causes an increase in the indicator studied as well as an anatomical expansion of indicator beyond the normal, resting range of visceral input to the spinal cord. Figure 9 illustrates this point for the

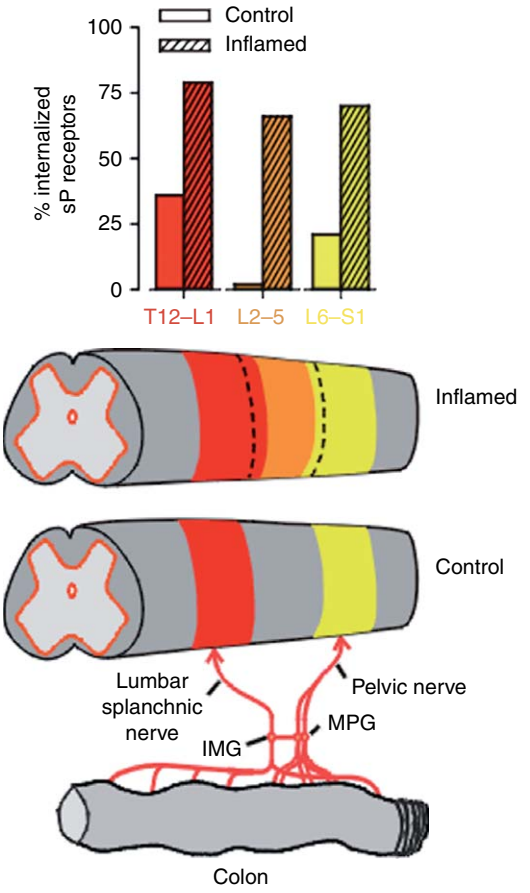

Figure 9 Internalization of substance P (sP) receptors by colon distension in the absence (control) and 3 h following intracolonic instillation of zymosan (inflamed). In the absence of colon insult (control), noxious colon distension (80 mm Hg, 20 s) leads to internalization of the sP receptor in superficial spinal laminae in an anatomically appropriate distribution (i.e., T12–L1 and L6–S1 spinal segments via the lumbar splanchnic nerve and pelvic nerve innervations of the rat colon – there is no receptor internalization in lumbar spinal segments 2–5). Three hours after intracolonic instillation of an inflamogen, zymosan (inflamed), a time at which responses to colon distension are significantly increased (i.e., colon hypersensitivity is present behaviorally), the amount of sP receptor internalized (quantified at top) is significantly increased and now includes L2–5. IMG, inferior mesenteric ganglia; MPG, major pelvic ganglion. Adapted from Honoré , P., Kamp, E. H., Rogers, S. D., Gebhart, G. F., and Mantyh, P. W. 2002. Activation of lamina I spinal cord neurons that express the substance p receptor in visceral nociception and hyperalgesia. J. Pain 3, 3–11.

spinal cord, showing that internalization of the substance P receptor produced by colon distension increases significantly after colon insult and, moreover, now includes an area of the spinal cord that showed no receptor internalization after colon distension in the absence of insult (Honoré, P. *et al.*, 2002). This representation of central sensitization occurred within hours after colonic insult, revealing that mechanosensitive colon afferents sensitize, sleeping afferents awaken, and the visceral innervation and second-order neurons upon which the afferents terminate are rapidly and easily modified (i.e., are highly plastic). Other studies in rats show rapid changes in supraspinal sites as well, suggesting their involvement in states of increased central excitability (e.g., Coutinho, S. *et al.*, 1998). Central sensitization also affects somatic and visceral inputs that converge on spinal neurons, as shown by reduced thresholds for hindpaw withdrawal after bladder or colon insult (Jaggar, S. I. *et al.*, 1999; Miranda, A. *et al.*, 2004; Lamb, K. *et al.*, 2006). Such data obtained in animals are consistent with results from human studies. For example, repetitive colorectal distension increases pain perception and the area of cutaneous pain referral in normals (Ness, T. J. *et al.*, 1990) as well as patients with functional bowel disease (Munakata, J. *et al.*, 1997). Similarly, infusion of 0.15 M hydrochloric acid into the distal esophagus not only reduces stimulus threshold in the distal esophagus, but also in the nonacid-exposed esophagus as well as on the chest wall area of referral within an hour after acid exposure (Sarkar, S. *et al.*, 2000; 2001), again revealing that central sensitization produced by a visceral input is also apparent in the area of somatic referral.

Another expression of central sensitization, which can reflect either spinal or supraspinal involvement, is sensitization that develops between organs with inputs onto spinal dorsal horn neurons within the same spinal segments, an expression of viscero-visceral convergence (e.g., urinary bladder and colon), or between organs that do not share patterns of spinal segmental overlap. The former are easy to understand anatomically, and while not rigorously studied in the human population, patients with functional bowel disorders often also complain about pelvic pain or symptoms consistent with interstitial cystitis (Whitehead, W. *et al.*, 2002). Conversely, many patients with interstitial cystitis also suffer from functional bowel disorders (Alagiri, M. *et al.*, 1997). In nonhuman animals, it has been established that colon inflammation triggers bladder hyperactivity (Pezzone, M. A. *et al.*, 2005) and, conversely, that cystitis produces colon hypersensitivity (Lamb, K. *et al.*, 2006; Winnard, K. P. *et al.*, 2006).

Animal and human studies have clearly established the contribution of supraspinal sites to sensitization to visceral input. In susceptible rodent strains, stress enhances behavioral responses to visceral distension (Coutinho, S. V. *et al.*, 2002; Bradesi, S. *et al.*, 2005). While multiple mechanisms may contribute to this modulation of visceral input, descending inhibitory or facilitatory pathways likely play a role (see below), as shown by the effects of electrical stimulation within the rostral ventromedial medulla on responses to noxious colorectal distension (Zhuo, M. and Gebhart, G. F., 2002) and of selective abolition of descending facilitatory influences in a model of rodent pancreatitis (Vera-Portocarrero, L. P. *et al.*, 2007). These reports are consistent with data obtained in human volunteers. Activation of descending inhibitory mechanisms through heterotopic stimulation blunted perception of rectal distension in healthy volunteers (Song, G. H. *et al.*, 2006). Conversely, uncomfortable visceral input triggered by acid infusion into the duodenum lowered the pain threshold to proximal esophageal stimulation (Hobson, A. R. *et al.*, 2004). These experiments also support a rapid involvement (minutes to hours) of supraspinal sites in central sensitization. Longer-term evidence of supraspinal contributions to central sensitization is provided by both clinical reports of esophageal or gastric hypersensitivity in patients with IBS (or somatic disorders like fibromyalgia) (Price, D. D. *et al.*, 2007a; 2007b; Sharma, A. and Aziz, Q., 2007) and by various manipulations limited to the neonatal period that lead either to visceral hypersensitivity or increased susceptibility to organ insult in adult animals. In rats, neonatal colon irritation (intracolonic mustard oil) or colon distension (Al Chaer, E. D. *et al.*, 2000), urinary bladder inflammation (intravesical zymosan, Randich, A. *et al.*, 2006), maternal separation (a stressor, Coutinho, S. V. *et al.*, 2002), or neonatal immune challenge with the bacterial endotoxin lipopolysaccharide (Spencer, S. J. *et al.*, 2007) are all associated with increased organ sensitivity in the adult animal. Because these experimental neonatal manipulations are not associated with adult organ inflammation, the adult visceral hypersensitivity in these models is considered to be maintained by central nervous system mechanisms, including dysregulation or reorganization (discussed in Section 5.37.4.3).

Mechanistically, both human and nonhuman animal studies have established an important role for peripheral, spinal (and supraspinal) *N*-methyl-D-aspartate (NMDA) receptors in central sensitization following visceral insult (e.g., McRoberts, J. A. *et al.*, 2001; Willert, R. P. *et al.*, 2004; see Woolf, C. J. and Thompson, S. W., 1991 for a general overview), although the relevant spinal neurons and signal transduction pathways in visceral sensory pathways are not revealed by these findings. The process of central sensitization is linked to long-term potentiation, which has been extensively studied in the hippocampus in relation to learning and memory, and in spinal cord exhibits similar characteristics that involve transcriptional and other events that lead to changes in excitability that can outlast the peripheral input. Although not focused on visceral inputs, these studies are based on features common to visceral nociceptive input: recordings from lamina I spinal dorsal horn neurons that project to the pontine parabrachial area and coactivation of substance P and NMDA receptors (Ikeda, H. *et al.*, 2003; 2006). Study of this population of spinal neurons, upon which visceral afferents likely terminate (along with nonvisceral nociceptive afferents), reveals synaptic plasticity dependent upon neuroactive substances contained and released from visceral afferent terminals in the spinal cord and a cellular process that likely contributes to induction of central sensitization.

5.37.4.3 Central Modulation of Visceral Pain

One consequence of peripheral events that lead to central sensitization is activation of endogenous pain modulatory systems and there is growing appreciation that visceral disorders characterized by persistent discomfort and pain reveal, at least in part, a dysregulated central nervous system. The concept that there exist endogenous mechanisms that modulate pain arose from studies showing that electrical stimulation or chemical activation (e.g., glutamate to activate cells or drugs like opioids acting at their cognate receptors) in the brainstem PAG produced powerful descending inhibitory effects on spinal nociceptive inputs. The initial focus of such studies was on inhibitory inputs descending from the brainstem and on modulation of noxious inputs. Presently, it is appreciated that descending influences require a relay in the rostral ventromedial medulla between the PAG and spinal cord, are not restricted to modulation of only noxious inputs, and importantly not limited to only inhibitory influences. Normally, descending modulation represents a balance between inhibitory and facilitatory influences, with inhibition typically dominant. Facilitatory influences, however, have been shown to predominate in some experimental conditions and have been hypothesized to contribute to maintenance of persistent pain states (Porreca, F. *et al.*, 2002; Gebhart, G. F., 2004). With respect to functional visceral disorders that persist in the absence of a defined pathobiology, and many of which are comorbidly expressed with other generalized disorders (e.g., fibromyalgia), the concept of a dysregulated modulatory system has gained both currency and experimental support.

Most nonhuman animal studies have examined nonvisceral pain, but several studies have confirmed for visceral inputs what has been more widely documented for nonvisceral inputs. Activation of brainstem sites (PAG and rostral ventromedial medulla) has been shown to facilitate visceromotor reflexes (Zhuo, M. and Gebhart, G. F., 2002) and spinal dorsal horn neuron responses (Zhuo, M. *et al.*, 2002) to noxious colon distension in the rat. Similarly, an experimental pancreatitis in rats has been shown to be maintained by facilitatory influences descending from the rostral ventromedial medulla (Vera-Portocarrero, L. P. *et al.*, 2007). These studies confirm that modulation of spinal nociceptive visceral transmission does not differ in character from modulation of nonvisceral inputs. Importantly, studies in humans suggest that facilitatory modulatory influences can contribute to persistent pain states, including visceral pain states. Such studies rely on interpretation of changes in patterns or intensity of brain imaging or on localization, wave form, and magnitude of event-related cortical potentials.

For example, Dimcevski G. *et al.* (2007) recently reported functional brain reorganization in chronic pancreatitis patients. They electrically stimulated at different sites from above the gastro-esophageal junction to the horizontal part of the duodenum and recorded event-related brain potentials from surface electrodes on the scalp and also assessed sensation. They found that neuronal sources in the insula were most consistently changed in chronic pancreatitis patients relative to healthy controls and concluded that reorganization in this part of the brain is a contributing mechanism to pain in chronic pancreatitis. This and other reports (e.g., Price, D. D. *et al.*, 2007a; 2007b) clearly reveal that central mechanisms are important to the maintenance of persistent visceral

pain conditions. Mechanisms by which the excitability of neurons in these or other brain areas might increase or decrease and be sustained are unknown. Stress and other external factors, as well as cognitive and emotional events, can contribute to activity in supraspinal sites and influence the interpretation of information arriving there from internal organs. The matrix of brain areas activated by painful visceral stimuli is similar to that seen during anticipation of such a painful stimulus, demonstrating the importance of cognitive influences (Yágüez, L. *et al.*, 2005). Stress activates the hypothalamic–pituitary–adrenal axis, resulting in the release of various neuroendocrine mediators. Studies in humans have demonstrated different neuroendocrine responses in patients with chronic visceral pain syndromes (Posserud, I. *et al.*, 2004). These mediators may directly or indirectly affect visceral sensory function (e.g., Taché, Y. *et al.*, 2004) and may function as targets for pharmacologic interventions.

5.37.5 Summary

(1) The principal conscious sensations that arise from the viscera are discomfort and pain. Typically, visceral pain is diffuse and difficult to localize, not distinctly felt at the source and instead referred to other tissues.

(2) Most experimental work in humans and nonhuman animals has utilized hollow organ distension, an adequate (in the Sherringtonian context) noxious visceral stimulus. Visceral inflammation and ischemia are also considered to be adequate stimuli, but they are more difficult to control experimentally and thus have been less widely used. It is generally held that pain cannot be produced from all viscera (e.g., the parenchyma of solid organs like the liver) or from organs that have only an afferent innervation (and not a sensory innervation), but new knowledge has expanded our understanding of visceral sensations and suggest that these and other issues of visceral insensitivity should be reevaluated.

(3) The innervation of the viscera is unique. Each organ is innervated by two nerves, either the vagus nerve and a spinal visceral nerve or a splanchnic nerve and the pelvic nerve, and the function(s) of each nerve differ. The route from the organ to the spinal cord of spinal visceral nerves involves transit of prevertebral ganglia, where axon collaterals of visceral nerves can influence organ function, as well as paravertebral ganglia. Vagal afferent fibers terminate centrally in the brainstem nucleus of the solitary tract.

(4) Cell bodies of the vagus nerves are contained in the nodose ganglia (primarily) and cell bodies of all other visceral nerves are contained in DRG. Generally, visceral sensory neuron cell bodies are larger in size than would be expected given that virtually all visceral sensory neurons have thinly myelinated or unmyelinated axons, which in the somatic realm are associated with small-diameter cell bodies.

(5) Spinal visceral nerves terminate in laminae I, II, V, and X, but importantly branch significantly within the spinal cord and extend both rostrally and caudally from the spinal segment of entry. Significantly, some terminations reach the contralateral side of the spinal cord.

(6) Most mechanoreceptors in viscera have low thresholds for response to stretch/tension (e.g., balloon distension), but a significant proportion ($\sim$20–30%) have high thresholds for response. The latter group fulfills criteria for nociceptors: their response threshold is in the noxious range (generally $\geq$30 mm Hg distending stimulus) and they encode stimulus intensity in the noxious range, but do not encode innocuous intensities of stimulation.

(7) Low-threshold visceral mechanoreceptors respond in the physiologic range, but in addition possess properties that suggest involvement in visceral discomfort and pain. Unlike low-threshold cutaneous mechanoreceptors, low-threshold visceral mechanoreceptors respond vigorously to noxious intensities of stimulation, continue to encode stimulus intensity into the noxious range, and sensitize (a defining characteristic of nociceptors). These properties are not unlike some low-threshold sensory neurons that innervate another deep tissue, muscle.

(8) Low-threshold visceral mechanoreceptors are normally and principally involved in afferent and reflex functions, but in conjunction with high-threshold visceral mechanoreceptors can contribute to intense acute visceral pain. In functional, inflammatory or ischemic visceral disorders, where sensitization develops and sleeping visceral nociceptors become active, we believe that all mechanosensitive visceral endings can contribute to uncomfortable and painful visceral sensation.

(9) Visceral sensory neurons sensitize and thereby contribute to central sensitization, a consequence of increased input to the central nervous system that is not limited only to the spinal cord. Tenderness to palpation and an increase in the area of referred sensation, respectively, mark peripheral and central sensitization.

(10) Functionally, visceral sensory neurons in the different innervations of the same organ are affected differently by sensitizing events. This perhaps should not be surprising given that the proportions and distributions of mechanosensitive endings of the two innervations differ significantly for the organs studied to date. This is a developing area of investigation that has the potential to lead to therapeutic strategies targeting a selective innervation of a viscus.

(11) Brainstem modulatory circuitry normally exerts an inhibitory influence on spinal pain transmission. Increased visceral input from sensitized receptors initiates processes of sensitization in both spinal and supraspinal sites, which can alter the balance between descending inhibitory and facilitatory influences on spinal pain transmission. In cases of long lasting visceral hypersensitivity (e.g., functional bowel disorders), the hypothesis that the hypersensitivity is maintained by supraspinal influences in the absence of sensitized visceral input is tenable.

5.38.1 Introduction

Recurrent abdominal pain or discomfort in the absence of detectable structural or biochemical abnormalities, associated with alterations in bowel habits, are the principal symptoms of irritable bowel syndrome (IBS) (Drossman, D. A. *et al.*, 2002). Due to the likely heterogeneity of the syndrome (Mayer, E. A. and Collins, S. M., 2002) and the lack of reliable organic markers, the development of a unifying, and generally agreed upon, hypothesis of the pathophysiology of IBS has remained an elusive goal. Many investigators in the field agree that an enhanced perception of physiologically occurring, or experimentally generated visceral events (visceral hypersensitivity) (Mayer, E. A. and Gebhart, G. F., 1994; see Vagal Afferent Neurons and Pain and Visceral Pain) in conjunction with alterations in gastrointestinal motility and secretory function, are key pathophysiological mechanisms underlying the cardinal clinical features of IBS. In contrast, many other alterations reported in IBS patients over the past decades, including altered mucus production and altered gastrointestinal motility, have turned out to be epiphenomena which are unlikely to be essential for symptom generation. Considerable evidence supports the role of psychosocial (Bennett, E. J. *et al.*, 1998; Collins, S. M., 2002) and physical (Gwee, K. A. *et al.*, 1996) (i.e., acute gastroenteric infections) stressors as central and peripheral triggers of first symptom onset or symptom exacerbation of long-standing IBS (Mayer, E. A. *et al.*, 2001), and an IBS hypothesis of hyperresponsiveness of central stress circuits has been proposed (Mayer, E. A. and Collins, S. M., 2002).

5.38.2 Clinical Presentation and Epidemiology

IBS is one of the most common and most thoroughly studied functional disorders of the gastrointestinal tract (Drossman, D. A. *et al.*, 2002). In additional to chronic abdominal pain, the clinical presentation of IBS typically also includes nonpainful abdominal discomfort (sensations of urgency, bloating, fullness, gas and constipation) (Lembo, T. J. and Fink, R. N., 2002) and visible abdominal distension. These gastrointestinal symptoms are frequently associated with extraintestinal symptoms such as fatigue, decreased energy level, impaired sleep, depression, and anxiety (Zimmerman, J., 2003). In the absence of generally agreed upon reliable biological markers, the diagnosis of IBS remains one based on the presence of the so-called symptom criteria (Thompson, W. G. *et al.*, 1999). The most widely accepted diagnostic criteria are the Rome II Criteria that evolved from the Rome I and the Manning criteria initially defined about a decade ago (Longstreth, G. F., 2005). Different IBS patient subtypes have been identified based on their bowel habit predominance and have been classified as: constipation, diarrhea, or alternating periods of both. In a large US sample, approximately 50% of IBS patients present alternating bowel habit (IBS-A),

30% diarrhea (IBS-D), and 20% constipation (IBS-C) (Tillisch, K. *et al.,* 2005).

Large population based studies in the US have found a prevalence of IBS of about 14% with a greater proportion of women affected (female-to-male ratio approximately 3:1 to 3:2). The socioeconomic consequences of IBS are considerable with a large impact on work productivity and absenteeism (Dean, B. B. *et al.,* 2005). In addition, a substantial reduction in health-related quality of life (HRQoL) has been observed in IBS patients with moderate to severe symptoms who are seen in a referral setting compared with healthy controls (Spiegel, B. M. *et al.,* 2004). Interestingly, bowel habit alterations contributed little to the HRQoL impairment in this study, while extraintestinal manifestations such as loss of energy, fatigue, and excessive worry were important determinants. The annual cost of IBS in the US has been estimated to be between $1.7 billion and $10 billion in direct medical cost (repetitive use of multiple healthcare resources) and $20 billion for indirect costs (work absenteeism and impaired productivity) representing a high socioeconomic burden on society (Inadomi, J. M. *et al.,* 2003).

While research over the past few years has provided significant advances in the understanding of IBS pathophysiology, the precise mechanism(s) underlying symptom generation remains incompletely understood, generating considerable controversy among investigators. As a result, the development of effective IBS therapies has been slow and disappointing (Bradesi, S. *et al.,* 2006). IBS pathophysiology is often viewed within the so-called biopsychosocial model in which altered physiology (gastrointestinal motility and secretion, enhanced perception of visceral stimuli (visceral hypersensitivity) and psychosocial factors interact and determine the clinical expression of IBS (Schwetz, I. *et al.,* 2004). From a biological perspective, IBS symptomatology can be viewed as the manifestation of alterations in the brain–gut axis, specifically as a dysregulation in the complex interplay between events occurring within the gut, the enteric nervous system, and the central nervous system (Mulak, A. and Bonaz, B., 2004).

5.38.3 The Bidirectional Brain–Gut Axis Model

Brain-gut interactions play a prominent role in the modulation of gut function in health and disease (Mayer, E. A. *et al.,* 2001; Taché, Y. *et al.,* 2001). Therefore, every conceptual model of IBS has to take into account that neither the central nervous system nor the gastrointestinal tract function in isolation, but that both systems interact with each other under normal conditions and particularly during perturbations of homeostasis. Afferent signals arising from the lumen of the gut are transmitted via various visceral afferent pathways (enteric, spinal, vagal) to the central nervous system. Homeostatic reflexes, which generate appropriate gut responses to physiological as well as pathological visceral stimuli, occur at the level of the enteric nervous system, the spinal cord, and pontomedullary nuclei and limbic regions. Vagal visceral afferent inputs may also play an important role in such diverse functions as modulation of emotion, pain sensitivity, satiety, and immune response (Jänig, W. and Habler, H.-J., 2000). Whereas the reflex circuits within the enteric nervous system in principle can regulate and synchronize all basic gastrointestinal functions (motility, secretion, blood flow), coordination of gut functions with the overall homeostatic state of the organism requires continuous communication between the central nervous system and the gastrointestinal tract (Mayer, E. A. and Collins, S. M., 2002). Descending cortico-limbic influences can set the gain and responsiveness of these reflexes, or impose distinct patterns of motor responses on lower circuits, should the overall condition of the body make it necessary. Such top-down override of local reflex function occurs during sleep, during the stress response, or during strong emotions such as fear and anger (Ito, M., 2002; Mayer, E. A., 2000a; Taché, Y. *et al.,* 2001; Welgan, P. *et al.,* 1988). While the great majority of homeostatic afferent input from the gut (as well as other viscera) to the central nervous system is not consciously perceived, there are both peripheral and central adaptive mechanisms which can result in enhanced perception and altered reflex responses to visceral stimuli (Mayer, E. A. and Gebhart, G. F., 1994).

5.38.4 Visceral Hypersensitivity

The initial clinical observations that led to the hypothesis that IBS patients exhibit visceral hypersensitivity include recurring abdominal pain, tenderness during palpation of the sigmoid colon during physical examination, and excessive pain during endoscopic evaluation of the sigmoid colon (Mayer, E. A. and Gebhart, G. F., 1994). Multiple human experimental studies using barostat-controlled balloon distension

paradigms have reported lowered colorectal perceptual thresholds, increased sensory ratings and viscerosomatic referral areas in IBS patients compared to healthy individuals (Bouin, M. *et al.,* 2002; Chang, L. *et al.,* 2000a; Mertz, H. *et al.,* 1995). Despite the uncertainty about the underlying mechanism(s), this kind of experimentally induced visceral hypersensitivity has been considered a pathophysiological hallmark of the disease. Within the framework of homeostatic afferents, the finding of chronic, conscious awareness of unpleasant visceral sensations, together with the presence of altered reflex regulation in the gut, could be explained by several different mechanisms, including the following: (1) a peripheral up-regulation of the sensitivity of visceral afferent pathways which may be related to alterations in the activity of various effector cells within the gut (enteric nerves, enterochromaffin cells, immune cells); (2) a spinal or brainstem alteration in the sensitivity to incoming visceral afferents which could be a consequence of primary peripheral or central inputs; or (3) a primary central amplification of perceptual and reflex responses to incoming visceral afferent signals. In addition, the frequent presence of compromised vital functions such as sleep, mood, sexual drive, and affect, suggest a possible involvement of other homeostatic mechanisms, such as tonic serotonergic pontomedullary systems (Mason, P., 2005). It remains to be determined if these various abnormalities occur in distinct subsets of patients, at different stages of the disorder, or if various combinations of them generate a heterogeneous patient population.

5.38.4.1 Peripheral Up-Regulation of Visceral Afferent Sensitivity

The concept that gut mucosal alterations may play a role in the pathophysiology of IBS has been prompted by several lines of clinical and preclinical evidence including: (1) alterations in the number of immune cells, particularly mast cells, within intestinal biopsies of patients meeting diagnostic criteria for IBS (Barbara, G. *et al.,* 2004; O'Sullivan, M. *et al.,* 2000; Weston, A. P. *et al.,* 1993), and the demonstration in rodent studies that mucosal mast cells play a prominent role of transducers within the brain–gut axis (Santos, J. *et al.,* 2005; Soderholm, J. D. *et al.,* 2002; Wilson, L. M. and Baldwin, A. L., 1999); (2) demonstration of visceral hypersensitivity in different animal models of gut immune system activation (Barbara, G. *et al.,* 1997; Barreau, F. *et al.,* 2004; La, J. H. *et al.,* 2003; Lamb, K. *et al.,* 2006); (3) preliminary evidence that supernatants from human mucosal biopsies (taken from IBS patients) have a unique effect on visceral afferent function in rodent bioassays (Barbara, G. *et al.,* 2005a; Barbara, G. *et al.,* 2005b); (4) the development of IBS-like symptoms in a small number of individuals following an episode of acute gastroenteritis (Gwee, K. A. *et al.,* 1998; Spiller, R. C., 2005) and in a subset of patients with inflammatory bowel disease (Bernstein, C. N. *et al.,* 1996); (5) evidence for alteration in the normal gut flora (including bacterial overgrowth) (Balsari, A. *et al.,* 1982; O'Leary, C. and Quigley, E. M., 2003; Swidsinski, A. *et al.,* 1999); and (6) therapeutic responses to treatment with antibiotics and probiotic treatments (Madden, J. A. and Hunter, J. O., 2002; Pimentel, M. *et al.,* 2000, 2003). Without discussing this large body of evidence supporting each of these points (Barbara, G. *et al.,* 2006; Crowell, M. D. *et al.,* 2005; Schwetz, I. *et al.,* 2003; Spiller, R. C., 2005), it is assumed, by many investigators focusing on peripheral etiologies of visceral hypersensitivity, that the mucosal immune activation plays some role in maintaining a chronic state of visceral afferent sensitization. Based on recent preclinical evidence, it is conceivable that transient peripheral sensitization may result in long-lasting up-regulation of spino-bulbo-spinal pain amplification mechanisms (Suzuki, R. *et al.,* 2005). While such peripheral mechanisms (in particular an increase in mucosal mast cells and intestinal enterochromaffin cells) may play an important role in a subset of IBS patients, or in the mediation of certain types of IBS symptoms, a series of observations argues against a simple relationship between peripheral mucosal events and IBS symptoms. For example, it has long been known that some patients in remission from inflammatory bowel disease, especially ulcerative colitis, report symptoms similar to those of IBS patients (Isgar, B. *et al.,* 1983; Simren, M. *et al.,* 2000). In contrast, inflammatory bowel disease patients (without associated IBS features) who have chronically recurring gut inflammation do not exhibit visceral hypersensitivity (Chang, L. *et al.,* 2000b) or enhanced central nervous system responses to visceral distension during periods of remission (Loennig-Baucke, V. *et al.,* 1989; Rao, S. S. C. *et al.,* 1987). In addition, clinical states characterized by chronic inflammation of the esophagus (gastroesophageal reflux disease) and stomach (*Helicobacter pylori* chronic gastritis) are also not associated with visceral mechanical hyperalgesia (Fass, R. *et al.,* 1998; Mertz, H. *et al.,* 1998). On the contrary, it has been reported that

Crohn's patients with isolated inflammation in the small bowel have elevated discomfort thresholds to controlled distension of the rectum (Bernstein, C. N. *et al.,* 1996), and that patients with ulcerative colitis do not show sensitization following repetitive noxious distension of the sigmoid colon (Chang, L. *et al.,* 2000b). Taken together, these data are consistent with the interpretation that chronic mucosal inflammatory changes in the esophagus, stomach, or colon by themselves do not necessarily result in mechanical visceral hypersensitivity. Chronic intestinal inflammation in inflammatory bowel disease seems to be associated with the activation of counterregulatory antinociceptive systems, inhibition of pain facilitatory pathways or both, resulting in a reduced perception of visceral afferent information (Chang, L. *et al.,* 2000b). One may speculate that genetic polymorphisms recently identified as being associated with greater pain sensitivity may be related to such compromised endogenous pain modulation systems (Diatchenko, L. *et al.,* 2005).

5.38.4.2 Spinal and Supraspinal Up-Regulation of Visceral Afferent Sensitivity

A growing body of literature supports the concept of an enhanced stress responsiveness playing a role in the development of IBS symptoms in a subset of patients (reviewed in Mayer, E. A., 2000b; Mayer, E. A. *et al.,* 2001). An individual's response to stress (perturbation of homeostasis) is generated by a central network comprised of integrative brain structures, referred to as the emotional motor system (EMS) (for a detailed review see Mayer, E. A., 2000b); Mayer, E. A. *et al.,* 2001). The main output systems of the EMS are ascending monoaminergic pathways, the autonomic nervous system, the hypothalamic–pituitary–adrenal axis and endogenous pain modulatory systems. The neuropeptide, corticotropin-releasing factor (CRF), plays a prominent role in integrating these various outputs in response to physical and psychological stressors (Bale, T. L., 2005).

The responsiveness of the EMS and its various output pathways is under partial genetic control (Pezawas, L. *et al.,* 2005) and is programmed by prenatal (Matthews, S. G., 2002) and postnatal (Ladd, C. O. *et al.,* 2000) aversive events and by certain types of pathological stress (Fuchs, E. and Fluegge, G., 1995). In humans, early (pre- and postnatal) life adverse experiences can lead to long-lasting stress hyperresponsiveness, which in turn has been associated with a wide range of health impairments in adult life (Whitehead, M. and Holland, P., 2003). Long-term consequences of early aversive events also include an increased vulnerability for stress-sensitive disorders such as IBS and posttraumatic stress disorder (Lowman, B. C. *et al.,* 1987). Stress hyperresponsiveness is related in part to permanent, stress-induced hypersecretion of CRF (Heim, C. *et al.,* 2000). A number of preclinical studies support the concept of centrally mediated alteration of visceral perception. Different stress paradigms were found to lead to enhanced visceral response to colonic distension (Bradesi, S. *et al.,* 2002; Gue, M. *et al.,* 1997; Schwetz, I. *et al.,* 2005), which can be mimicked or abolished by central administration of pharmacological agents. For example, central CRF injection was found to mimic the effect of stress on visceral sensitivity, whereas stress-induced visceral hyperalgesia may be reduced by central injection of a CRF receptor subtype 1 antagonist (Taché, Y. *et al.,* 2004). Similarly, a neurokinin-1 receptor antagonist injected into the spinal cord in stress-sensitized guinea pigs (Greenwood-Van Meerveld, B. *et al.,* 2003) or rats (Bradesi, S. *et al.,* 2005) abolished the stress-induced visceral hyperalgesia to colorectal distension. Together, the data available suggest the role of central stress circuits in the alteration of visceral nociceptive response in animal models for IBS. In contrast to the well-known analgesic response to severe acute stressors (stress-induced somatic analgesia), prolonged and milder stressors that are associated with anxiety-like states are commonly associated with hyperalgesic responses (Boccalon, S. *et al.,* 2006; Vendruscolo, L. F. *et al.,* 2004).

Suggestive evidence for an alteration in central pain modulation mechanisms in IBS patients comes from a series of functional brain-imaging studies. In response to rectal balloon distension, IBS patients have shown increased activation of subregions of the dorsal anterior cingulate cortex (ACC) (Naliboff, B. D. *et al.,* 2001b; Porreca, F. *et al.,* 2002; Verne, G. N. *et al.,* 2003), a brain region involved in attentional and emotional modulation of stimulus perception (Petrovic, P. and Ingvar, M., 2002). Dorsal ACC subregions provide input to subcortical endogenous pain inhibitory circuits (Petrovic, P. and Ingvar, M., 2002), as well as to subcortical pain facilitatory circuits (Zhuo, M. and Gebhart, G. F., 2002). The relative balance between these simultaneously activated pain modulation systems determines the overall modulation of perception (Porreca, F. *et al.,* 2002). Thus, the finding of greater dorsal ACC

activation by a visceral stimulus in IBS may be related to greater attention and possibly associated activation of pain facilitation circuits to a visceral stimulus in IBS. On the other hand, the lesser activation of the periaqueductal gray (PAG) reported in some studies (Naliboff, B. D. *et al.,* 2001b) is consistent with possible deficiencies in the cortical activation of endogenous pain inhibition systems. Several recent studies (Chang, L., 2005) provide further support for the hypothesis of altered endogenous pain modulation in IBS patients. In one study (Mayer, E. A. *et al.,* 2005), IBS patients were compared to patients with ulcerative colitis and with healthy control subjects. IBS patients showed consistently greater activation of limbic/paralimbic brain regions (amygdala, hypothalamus, ventral/rostral ACC, dorsomedial prefrontal cortex) suggestive of increased activation of arousal circuits by a visceral stimulus. In addition, the results showed activation in the ulcerative colitis and control subjects, but not in IBS patients, in the lateral prefrontal regions and a midbrain region including the PAG. A connectivity analysis using structural equation modeling supported these regions acting as part of a pain inhibition network that involves lateral and medial prefrontal influences on the PAG. Another study provided evidence for the abnormal activation of diffuse noxious inhibitory control systems in response to a noxious stimulus in IBS patients (Wilder-Smith, C. H. *et al.,* 2004).

Several lines of evidence indicate that patients with IBS and other functional disorders have hypervigilance for symptom relevant sensations (Berman, S. M. *et al.,* 2002). In a recent longitudinal study of IBS patients exposed to six sessions of rectal inflations over a 1-year period, regional cerebral blood flow to the inflations and anticipation of inflations using $H_2^{15}O$ positron emission tomography (PET) at the first and last session were evaluated (Naliboff, B. D. *et al.,* 2001a). Subjective ratings of the rectal inflations normalized over the course of the study consistent with decreased vigilance towards the visceral stimuli. Stable activation of the central pain matrix (including thalamus and insula) by the rectal stimulus was observed over the 12-month period, while activity in limbic, paralimbic ,and pontine regions decreased. An analysis examining the co-variation of these brain regions supported the hypothesis of changes in an arousal network including limbic, pontine, and cortical areas underlying the decreased perception seen over the multiple stimulation studies.

5.38.5 Treatment Options

Despite its high prevalence and considerable impact on patients' HRQoL, treatment options for IBS continue to be limited and there are few well designed studies to support the effectiveness of some of the most commonly used therapies (for review see Camilleri, M., 2004). Traditional treatment algorithms have primarily been aimed at peripheral targets and are largely symptom-based (e.g., laxatives, antidiarrheals, prokinetics). In addition, centrally targeted therapies include various forms of cognitive behavioral therapy (Hutton, J., 2005), low-dose tricyclic antidepressants (Drossman, D. A. *et al.,* 2003) and, in patients with co-morbid psychiatric conditions, full dose serotonin reuptake inhibitors (Creed, F. *et al.,* 2003). A series of compounds are currently in development, which is targeted at central circuits involved in stress responsiveness and pain modulation (Bradesi, S. *et al.,* 2006).

5.38.6 Summary and Conclusions

Despite its high prevalence, and considerable burden of illness, treatment of IBS remains unsatisfactory. However, considerable progress has been made to identify alterations at different levels of the brain–gut axis which may contribute to characteristic symptoms. In the absence of generally agreed upon animal models of the syndrome, functional brain-imaging techniques in well defined human patient populations has a high promise to identify central abnormalities related to altered stress responsiveness and associated pain modulation circuits. A number of novel treatment approaches aimed at these central abnormalities are currently under development.

Glossary

dysmenorrhea Painful cramping of the lower abdomen occurring before or during menses primarily as a result of endogenous prostaglandins, often accompanied by other symptoms such as sweating, tachycardia, headaches, nausea, vomiting, diarrhea, and tremulousness.

dyspareunia Painful intercourse.

epidural analgesia Regional analgesia produced by injection of local anesthetic solution into the peridural space.

postpartum pain Pain after childbirth; the postpartum period starts immediately following childbirth but the length of the period is not well defined.

referred pain Pain perceived in a region different from the injured area during the time of injury.

stages of labor pain There are three stages of labor pain. Stage 1 begins with regular uterine contractions and ends with complete cervical dilatation at 10 cm. Stage 2 begins once the cervix has completely dilated and ends with delivery of the fetus. Stage 3 lasts from the delivery of the fetus until the delivery of the placenta.

5.39.1 Introduction

The experience of pain during childbirth is a complex, multidimensional response to sensory stimuli generated during labor and delivery. Pain in childbirth occurs in the context of an individual woman's physiology and psychology, as well as in the context of the sociology of the culture and the health care system and its providers surrounding her. For the majority of women in all societies and cultures, natural childbirth is likely to be one of the most painful events in their lifetime. Average pain scores for labor pain are exceeded only by those for causalgia in chronic-pain patients and amputation of a digit in acute-pain patients (Melzack, R., 1984). Different from other acute and chronic pain experiences, pain during childbirth is not associated with a pathological process. It is surprising that this physiological process associated with the most basic and fundamental life experience causes severe pain, and this has been the subject of many philosophic and religious debates. The International Association for the Study of Pain (IASP) defines pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage (Merskey, H., 1979). Traditionally, different approaches to pain management of the pain in childbirth have addressed either the sensory or the affective dimension of

pain, while more recently a multidimensional approach has been advocated, addressing both dimensions of labor pain (Lowe, N. K., 2002; Melzack, R., 1984).

5.39.2 Physiological Aspects of Labor Pain

Compared to many other pain conditions, research on the neurophysiological mechanisms of pain in childbirth has been sparse, due to the difficulty of developing animal models that could be studied adequately using electrophysiological and neuroanatomical techniques. Studies examining the influence of pregnancy on somatosensory responses in animals and humans have shown hypoalgesia in late pregnancy prior to the onset of labor and this chance in nociceptive threshold is at least in part opioid-mediated (Bajaj, P. *et al.*, 2002; Jarvis, S. *et al.*, 1997). There are three distinct stages of labor pain related to uterine contractions, cervical stretching, and distension of the vaginal canal during fetal descend (for reviews see: McDonald, J. S., 2001; Rowlands, S. and Permezel, M., 1998). The first stage begins with regular uterine contractions and ends with complete cervical dilatation at 10 cm. Stage 1 has been further subdivided into an earlier latent phase and an ensuing active phase, which begins at about 3–4 cm of cervical dilatation and heralds a period of more rapid cervical dilation. Once the cervix has completely dilated, stage 2 of labor has begun. It ends with delivery of the fetus. Stage 3 of labor lasts from the delivery of the fetus until the delivery of the placenta. Pain during the first stage of labor (dilatation phase) is thought to be due to nociceptive stimuli arising from mechanical distension of the lower uterine segment and cervical dilatation. In addition, high-threshold mechanoreceptors in the myometrium may be activated in response to uterine contractions. Several chemical nociceptive mediators have been suggested, including bradykinines, leukotrienes, prostaglandins, serotonin, lactic acid, and Substance P. Pain of the first stage of labor is predominantly mediated by neural pathways involving the T10 to L1 spinal cord segments. Similar to other types of visceral pain, labor pain may present with referred pain to somatic structures in corresponding myotomes and dermatomes, including the abdominal wall, lumbosacral region, iliac crests, gluteal areas and thighs. Pain in the second and third stages of labor involves spinal cord segments S2 to S4, and is considered to be due to distension and traction on pelvic structures surrounding the vaginal vault and from distension of the pelvic floor and perineum. The mean intensity of pain in childbirth has been reported to be positively correlated with the intensity, duration, and frequency of uterine contractions and with the degree of cervical distension.

Pain associated with childbirth provokes a generalized stress response, which has widespread physiological and potentially adverse effects on the progress of labor and the well-being of the mother and the fetus (Brownridge, P., 1995; Beilin, Y., 2002). Respiratory effects include hyperventilation, which might lead to maternal hypocarbia and respiratory alkalosis, and rise in cardiac output, peripheral resistance, and blood pressure. Pain associated with uterine contraction results in stimulation of the release of stress-related hormones from the adrenal sympathetic axis and the hypophyseal–pituitary axis. Labor pain promotes maternal and fetal acidosis, which is due to a catecholamine-induced shift toward lipolytic metabolism, hyperventilation, physical exertion, starvation, and diminished buffering capacity secondary to respiratory alkalosis. While these effects may be largely innocuous during the course of uncomplicated labor, they present a great risk in the presence of certain medical and obstetric complications and in situations where fetal compromise already exists.

5.39.2.1 Variables Associated with the Severity of Labor Pain

There is a very high level of individual variability in the severity of labor pain and this has been correlated with several factors (Melzack, R., 1984; Brownridge, P., 1995). Primiparas and younger women report more pain than multiparas and older women. Women of higher socioeconomic status report less pain than women of lower socioeconomic status. In addition physical factors might play a role in increased pain ratings during labor, including increased fetal size and increased maternal body weight. Labor pain is influenced by maternal positions – women experience more pain when delivering in the horizontal position as compared to the upright position. Childbirth at night has been reported to be less painful than childbirth during the day. Women with a history of dysmenorrhea report higher pain levels during labor as compared to women, who do not have a history of menstrual pain. In contrast, a previous history of

nongynecological pain is correlated with decreased labor pain.

Severe fear of pain associated with childbirth occurs in 6–10% of parturients and is highly correlated to pain levels reported during the first stage of labor (for review see Saisto, T. and Halmesmäki, E., 2003). It is not an isolated variable, but associated with the woman's personal characteristics including general anxiety and fear of pain in general, low self-esteem, depression, dissatisfaction with her partnership, and lack of support. Fear of labor pain is strongly associated with fear of pain in general, independent of parity and is one of the most common reasons for requesting a cesarean section. Fear of childbirth has been reported to complicate about 20% of pregnancies in developed countries.

Although it is often assumed that culture and ethnicity have a significant influence on the intensity of labor pain, numerous studies have documented that there is no difference in self-report pain intensity ratings (see Lowe, N. K., 2002 for review). However, pain behavior is significantly influenced by culture and ethnicity, due to learned values and attitudes to the perception and expression of acute pain.

The environmental influences on pain perception have been explored in two prospective studies from Scandinavia comparing low-risk women delivering at birth centers and at standard obstetrical hospital-based units (Skibsted, L. and Lange, A. P., 1992; Waldenström, U. and Nilsson, C. A., 1994). These studies suggest that the environment provided may affect a woman's ability to cope with pain. While women delivering in birth centers reported significantly higher pain intensities than women delivering in hospital settings, there were no differences between the two groups with respect to satisfaction with the quality of the birth experience. These results emphasize the importance of differentiation between pain intensity and the attitude toward the pain experienced in labor and delivery.

It has been postulated that the memory for pain associated with disease, trauma, or surgical and medical procedures can be more damaging than its initial experience (Song, S.-O. and Carr, D. B., 1999). Although pain in childbirth is one of the most intense pains many women experience in their lifetime, childbirth is one of the most positive events of life for most women. Review of the literature on memory for labor pain shows that while memory of the events of childbirth is very accurate, the accuracy of recalled labor pain remains in question. Memories of labor pain can evoke intense negative reactions in a few women, but are more likely to give rise to positive consequences related to coping, self-efficacy and self-esteem (Niven, C. A. and Murphy-Black, T., 2000).

It is important to emphasize that labor pain, although being a very prominent aspect of childbirth, is just one aspect of the childbirth experience. A recent systematic review of the literature on pain and women's satisfaction with the experience of childbirth demonstrated that the influences of pain, pain relief, and intra-partum medical interventions on subsequent satisfaction are not as powerful as the personal expectations, the amount of support from caregivers, the quality of the caregiver-patient relationship, and involvement of decision making (Hodnett, E. D., 2002).

5.39.2.2 Treatment of Pain in Childbirth

5.39.2.2.1 Analgesia for Labor and Delivery

Analgesia for labor and delivery is now safer than ever and can be offered during all stages of labor, targeted to the individual needs and wishes of the pregnant woman, without compromising the safety of her or her unborn child (for reviews see Beilin, Y., 2002; Caton, D. *et al.*, 2002; Nystedt, A. *et al.*, 2004). Anesthesia related maternal mortality has decreased from 4.3 million live births during the years 1979–81 to 1.7 per million live births during the years 1988–90. The increased use of regional anesthesia techniques is partially responsible for this decrease in mortality. The most popular method for analgesia during labor and delivery is epidural analgesia using a combination of local anesthetics and opioids. Its popularity is related to its efficacy and safety. Drugs can be applied as continuous epidural infusions or as patient-controlled epidural analgesia. During the early stages of labor dilute solutions of local anesthetic can be used to achieve analgesia. As labor progresses, more concentrated solutions of local anesthetics can be used and opioids can be added. Typically the epidural catheter is inserted to maintain a low dermatomal level of analgesia for vaginal delivery (T10 to L1). If a cesarean section is required, the dermatomal level can be raised to T4. Combined spinal epidural techniques offer the advantage of a very rapid onset of analgesia with minimal motor block. The future of obstetric anesthesia lies in refining currently available drugs and techniques to make obstetric anesthesia even safer and more efficacious.

5.39.2.2.2 Nonpharmacological, complementary and alternative therapies for relief of pain in childbirth

Many nonpharmacological, complementary and alternative medicine methods exist to relieve labor pain (for reviews see Simkin, P. P. and O'Hara M., 2002; Smith, C. A. *et al.*, 2003; Cluett, E. R. *et al.*, 2004; Cyna, A. M. *et al.*, 2004; Huntley, A. L. *et al.*, 2004; Lee, H. and Ernst, E., 2004). These methods appeal to women and caregivers who are interested to reduce labor pain without creating potentially serious side-effects and high costs. In addition many women appreciate the simplicity of these approaches and the sense of control they gain from actively managing their pain. However, few of these therapies have been subjected to proper scientific study. Meta-analysis of randomized controlled trials has indicated that acupuncture and hypnosis may be beneficial for the management of pain in childbirth. There is evidence that water immersion during the first stage of labor reduces the use of analgesia and reported pain intensity, without adverse outcomes on labor duration, operative delivery, or neonatal outcomes. The effects of water immersion during the later stages of labor are not clear. No differences were observed for women receiving aromatherapy, music, or audio analgesia.

5.39.3 Pain during Pregnancy

While the focus of this review is on pain associated with childbirth, it is important to note that pain is also a significant issue during pregnancy (Stuge, B. *et al.*, 2003). Approximately 50% of women experience back pain and/or pelvic pain during their pregnancy, and in up to 15% of the cases the pain is rated as severe. Several hypotheses have been suggested to explain the etiology of this pain, including increased weight, decreased stability of the pelvic girdle due to hormonal changes and referred visceral pain mechanisms. The role of the hormone relaxin and pelvic pain in pregnancy is controversial. Physical therapy is often recommended for the prevention and treatment of these pregnancy-related pains, but the effects of these interventions have not been systematically studied and thus it is not clear if they are of any benefit to the pregnant women.

5.39.4 Postpartum Pain

While most of the discussion of adverse sequelae of labor and delivery has focused on urinary and fecal incontinence, there is now increasing awareness that pain associated with childbirth is not only related to the process of labor and delivery. Women report significant pains in many sites of the body after delivery, a phenomenon which has been defined as postpartum pain. Postpartum pains may include urogenital, pelvic, back and breast pains as well as headaches, persisting for months to years after labor and delivery (Audit Commission, 1997). It has been hypothesized that anesthetic techniques during labor and delivery and gonadal hormonal changes may play a role in the etiology of these pain complaints. Forty-nine percent of women report significant dyspareunia when resuming sexual intercourse after childbirth (Buhling, K. J. *et al.*, 2005). Women with a history of operative vaginal delivery have the highest prevalence of severe perineal pain when resuming sexual intercourse. The persistence of dyspareunia for longer than 6 months after delivery ranges from 3.4% to 14% based on mode of delivery. Treatment approaches for early intervention to prevent persistent perineal pain after childbirth have not been explored in detail. A meta-analysis assessing the effectiveness of topically applied anesthetics to the perineal region in the early postpartum period showed no compelling evidence of pain reduction (Hedayati, H. *et al.*, 2005). However, there has been no evaluation of the long-term effects of topically applied local anesthetics.

5.39.5 Future Aspects

Pain in childbirth is a complex, multidimensional experience. While the focus of this chapter is on the pain aspect of childbirth, it is important to keep in mind that pain is an important aspect, but not the only aspect of the childbirth experience. The acknowledgment of the existence of pain associated with labor and delivery and the recognition of the severity of this pain by the medical community over the last 50 years has resulted in a broad spectrum of pharmacological and nonpharmacological pain management options that can be offered to the parturient today. There have been tremendous advancements in the pharmacological treatment of pain in labor and delivery over the last 25 years, mainly due to

improved regional anesthesia techniques. The future of obstetric anesthesia lies in refining currently available drugs and techniques and in developing new drugs targeted at specific pathophysiological mechanisms to make obstetric anesthesia even safer and more efficacious. This will require translational research efforts ranging from basic science to clinical research. As a first step an animal model has recently been developed in the rat to study the neurophysiological and neuropharmacological mechanisms of pain associated with uterine cervical distension (Liu, B. *et al.*, 2005). Neuroanatomical studies of the sensory pathways from the uterine cervix have shown that P2X3-receptor-expressing sensory neurons might play a role during birthing and signal nociceptive information such as labor pain (Papka, R. E. *et al.*, 2005). Numerous nonpharmacological and alternative treatments are available for the treatment of pain in childbirth. While there is experience with some of those approaches already for centuries, many of these treatments have not been subjected to proper scientific study. Clinical studies assessing the effects of these interventions on pain in childbirth and on a woman's satisfaction with the childbirth experience, as well as studies assessing the effects on the safety for the pregnant woman and her child are urgently needed.

5.40.1 Urothelial Cells: Detectors of Mechanical, Chemical, and Thermal Stimuli

The urothelium is a specialized lining of the urinary tract, extending from the renal pelvis to the urethra. The urothelium is composed of at least three layers: a basal cell layer attached to a basement membrane, an intermediate layer, and a superficial apical layer with large hexagonal cells (diameters of 25–250 μm) which are also termed umbrella cells (Lewis, S. A., 2000; Apodaca, G., 2004). The umbrella cells, and, perhaps, intermediate cells may have projections to the basement membrane (Martin, B.F., 1972; Hicks M., 1975; Apodaca, G., 2004). Basal cells, which are thought to be precursors for other cell types, normally exhibit a low (3–6 months) turnover rate; however, accelerated proliferation can occur in pathology. For example, using a model (protamine sulfate) that selectively damages the umbrella cell layer has shown that the urothelium rapidly undergoes both functional and structural changes in order to restore the barrier following injury (Lavelle, J. *et al.*, 2002).

While the urothelium has been historically viewed primarily as a barrier, it is becoming increasingly appreciated as a responsive structure capable of detecting physiological and chemical stimuli, and releasing a number of signaling molecules. A number of investigators have described the release of diffusible mediators from the urothelium which could influence urinary bladder function (Ferguson, D.R. *et al.*, 1997; Hawthorn, M.H. *et al.*, 2000; Burnstock, G., 2001; Chess-Williams, R., 2002). There is now abundant evidence which indicates that urothelial cells display a number of properties similar to sensory neurons (nociceptors/mechanoreceptors) (see Table 1; Lewis, S. A. and Hanrahan, J. W., 1985; Birder, L. *et al.*, 1998; 2004; Smith, P. R. *et al.*, 1998; Birder, L. *et al.*, 2001; 2002a; 2002b; Chess-Williams, R., 2002; Beckel, J. *et al.*, 2004; Birder, L., *et al.*, 2004; Chess-Williams, R., 2004; Burnstock, G. and Knight, G. E., 2004; Murray, E. *et al.*, 2004; Tempest, H. V. *et al.*, 2004; Chopra, B. *et al.*, 2005; Birder, L. *et al.*, 2007) and that both types of cells use diverse signal transduction mechanisms to detect physiological stimuli.

5.40.1.1 Sensor Molecules Expressed in Urothelium Which Could Contribute to Bladder Pain

One example of a urothelial sensor molecule is the TRP channel, TRPV1, known to play a prominent role in nociception and in urinary bladder function (Szallasi, A., 2001). It is well established that painful sensations induced by capsaicin, the pungent substance in hot peppers, are caused by stimulation of TRPV1, an ion channel protein (Caterina, M. J. *et al.*, 1997; Caterina, M. J., 2001) which is activated by capsaicin as well as by moderate heat, protons, and lipid metabolites such as anandamide (endogenous ligand of both cannabinoid and vanilloid receptors). TRPV1 is expressed throughout the afferent limb of the micturition reflex pathway, Figure 1, including urinary bladder unmyelinated (C-fiber) nerves that detect bladder distension or the presence of irritant chemicals (Chancellor M. B. and de Groat, W. C., 1999). In the urinary bladder, TRPV1 is not only expressed by afferent nerves or myofibroblasts that form close contact with urothelial cells, but also by the urothelial cells themselves (Birder, L. *et al.*, 2001). Urothelial TRPV1 receptor expression correlates with the sensitivity to vanilloid compounds, as exogenous application of capsaicin or resiniferatoxin to cultured cells increases intracellular calcium and

Table 1 Examples of sensor molecules (i.e., receptors/ion channels) associated with neurons that have been identified in urothelial cells

Sensor function/stimuli	*Urothelial sensor molecules*	*Neuronal sensor molecules*
ATP	P2X/P2Y	P2X/P2Y
Capsaicin resiniferatoxin	TRPV1	TRPV1
Heat	TRPV1; TRPV2; TRPV4	TRPV1; TRPV2; TRPV3; TRPV4
Cold	TRPM8; TRPA1	TRPM8; TRPA1
H^+	TRPV1; ?	TRPV1; ASIC; DRASIC
Osmolarity	In part TRPV4	In part TRPV4
Bradykinin	B1; B2	B1; B2
Acetylcholine	Nicotinic/muscarinic	Nicotinic/muscarinic
Norepinephrine	α/β subtypes	α/β subtypes
Nerve growth factor	p75/trkA	p75/trkA
Mechanosensitivity	Amiloride sensitive Na^+ channels	Amiloride sensitive Na^+ channels

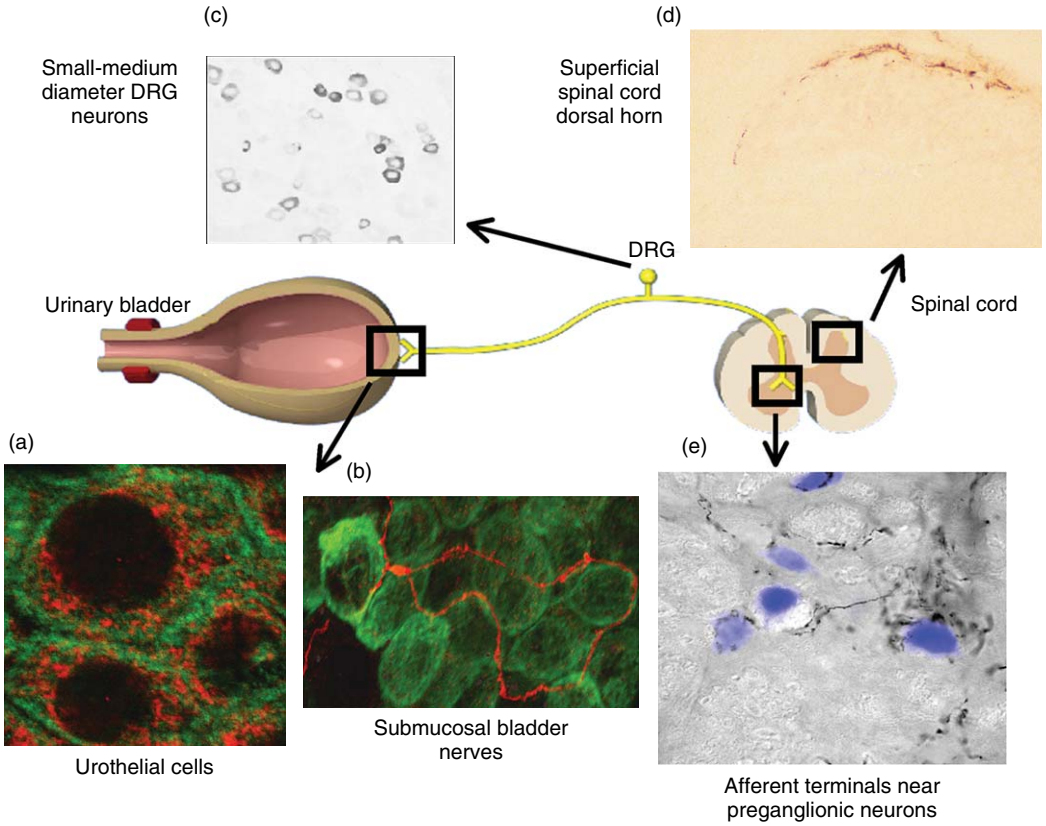

Figure 1 TRPV1 is expressed throughout the afferent limb of the micturition reflex pathway. TRPV1-immunoreactivity (cy-3, red) in basal epithelial cells (cyt 17, FITC green) (a); in nerve fibers (cy-3, red) located in close proximity to basal cells (FITC, green) (b) (punctate TRPV1 staining in urothelial cells was electronically subtracted to facilitate imaging of the TRPV1-immunoreactive nerve fiber); in small to medium diameter dorsal root ganglion (DRG) neurons (c); and in superficial regions of the spinal cord dorsal horn (d) (staining indicate TRPV1 nerve fibers). (e) TRPV1-positive afferent terminals (in black) are localized in close proximity to pre-ganglionic neurons (PGN neurons labeled by injection of a tracer dye, fast blue, into the major pelvic ganglion). Reproduced from Birder, L. A. 2005. More than just a barrier: Urothelium as a drug target for urinary bladder pain. Am. J. Physiol. Renal. Physiol. 289(3): F489–F495, used with permission from the American Physiological Society.

evokes transmitter (NO, nitric oxide; ATP, adenosine triphosphate) release (Birder, L. *et al.*, 2001; 2002a). In neurons, TRPV1 is thought to integrate/amplify the response to various stimuli playing an essential role in the development of inflammation-induced hyperalgesia (Ghuang, H. H. *et al.*, 2001; Holzer, P., 2004). Thus, it seems likely that urothelial TRPV1 might participate in a similar manner, in the detection of irritant stimuli following bladder inflammation or infection.

Anatomically normal, TRPV1-null mice exhibited a number of alterations in bladder urothelial cell function including a reduction of *in vitro*, stretch-evoked ATP release and membrane capacitance as well as a decrease in hypotonic-evoked ATP release (Birder, L. *et al.*, 2002a). These findings demonstrate that the functional significance of TRPV1 in the bladder extends beyond pain sensation to include participation in normal bladder function, and is essential for normal mechanically evoked purinergic signaling by the urothelium.

In addition to TRPV1, urothelial cells also express additional TRP channels, including TRPV2, TRPV4, TRPM8, and TRPA1. In contrast to TRPV1, TRPV2, and TRPV4, which are detectors of warm temperatures (TRPV4 can also be gated by hypotonic stimuli) (Liedtke, W. *et al.*, 2000; Alessandri-Haber, N. *et al.*, 2003; Chung, M. K. *et al.*, 2003), TRPM8 and TRPA1 have been shown to be activated by cold (25–28 °C) temperatures as well as by cooling agents (menthol, icilin) and are expressed in a subset of sensory neurons as well as in non-neural cells. This expression suggests that these cells express a range of thermoreceptors underlying both cold and heat stimuli (Stein, R. J. *et al.*, 2004). While the functional role of these thermosensitive channels in urothelium remains to be clarified, it seems likely that a primary role for these proteins may be to recognize noxious stimuli in the bladder. However, the diversity of stimuli which can activate these proteins suggests a much broader sensory and/or cellular role. For example, TRPM8 expression has been shown to be increased in some epithelia in malignant disorders (prostate tumors), suggesting a role in proliferating cells (Tsavaler, L. *et al.*, 2001). Thus, further studies are needed to fully elucidate the role of TRP channels in urothelium and their influence on bladder function.

Purinergic receptors, which are activated by ATP and related nucleotides, are known to play an important role in bladder function and chronic pain (Burnstock, G., 2001; North, R. A., 2004). Two families of purinergic receptors have been identified, P2X and P2Y, both of which are expressed in urothelial cells (Lee, H.Y. *et al.*, 2000; Birder, L. *et al.*, 2004; Tempest, H. V. *et al.*, 2004). Although the function of purinergic receptors in nonexcitable cells is less clear than in afferent neurons, the presence of such receptors may be associated with cell proliferation, apoptosis, secretion, and sensory transduction (Coutinho-Silva R. *et al.*, 2005; Greig, A. V. *et al.*, 2003). In the urinary bladder, recent studies have shown that urothelial-derived ATP release can act as a trigger for exocytosis, in part, via autocrine activation of urothelial purinergic (P2X; P2Y) receptors (Wang, E. C. *et al.*, 2005). This type of signaling may be similar to that in airway epithelium, where nucleotides released to the epithelial surface may act in a paracrine/autocrine manner to regulate ion transport and/or other functions via interactions with luminal epithelial purinergic receptors (Poulsen, A. N. *et al.*, 2005).

5.40.1.2 Response to Stimuli: Transducer Function of Urothelial Cells

Release of chemical mediators (NO, ATP, acetylcholine (ACh); substance P; prostaglandins (PG)) (Ferguson, D. R. *et al.*, 1997; Birder, L. *et al.*, 1998; Burnstock, G., 2001; Birder, L. *et al.*, 2003; Chess-Williams, R., 2004) from urothelial cells suggests that these cells exhibit specialized sensory and signaling properties that could allow reciprocal communication with neighboring urothelial cells as well as nerves or other cells (i.e., immune, myofibroblasts, inflammatory) in the bladder wall. Recent studies have shown that both afferent as well as autonomic axons are located in close proximity to the urothelium (Wayabayashi, Y. *et al.*, 1995; Birder, L. *et al.*, 2001). For example, peptide and TRPV1 immunoreactive nerve fibers have been found localized throughout the urinary bladder musculature and in a plexus beneath and extending into the urothelium. Confocal microscopy revealed that TRPV1 immunoreactive nerve fibers are in close association with basal urothelial cells such that their fluorescent signals overlapped within 0.5 μm optical sections. This type of communication suggests that these cells may be targets for transmitters released from bladder nerves or other cells, or that chemicals released by urothelial cells may also alter the excitability of bladder nerves.

Studies have demonstrated that ATP released from urothelium during bladder stretch could contribute to activation of bladder afferents.

That ATP released from urothelial cells during stretch can activate a population of suburothelial bladder afferents expressing $P2X_3$ receptors, signaling changes in bladder fullness and pain supports this idea (Ferguson, D. R. *et al.*, 1997; Burnstock, G., 2001). Accordingly, $P2X_3$ null mice exhibit a urinary bladder hyporeflexia, suggesting that this receptor and neural–epithelial interactions are essential for normal bladder function (Cockayne, D. A. *et al.*, 2000). This type of regulation may be similar to epithelial-dependent secretion of mediators in airway epithelial cells which is thought to modulate submucosal nerves and bronchial smooth muscle tone and may play an important role in inflammation (Homolya, L. *et al.*, 2000; Jallat-Daloz, I. *et al.*, 2001). Thus, it is possible that activation of bladder nerves and urothelial cells can modulate bladder function directly or indirectly via the release of chemical factors in the urothelial layer.

5.40.2 How Might Urothelial Cells Influence Pain Processes?

Recent evidence has demonstrated that urothelial cells exhibit plasticity whereby inflammation or injury can alter the expression and/or sensitivity of a number of urothelial-sensor molecules. Examples include changes in urothelial expression of various receptors including tyrosine kinase (trk), low-affinity nerve growth factor (p75), bradykinin, TRPV1, protease-activated receptors (PPARs), and purinergic receptor (P2X and P2Y) subtypes in animal models as well as in patients diagnosed with a number of bladder disorders including neurogenic bladder and interstitial cystitis (IC) – a chronic clinical disease characterized by urgency, frequency, and bladder pain upon filling (an innocuous stimulus) (Murray, E. *et al.*, 2004; North, R. A., 2004; Tempest, H. V. *et al.*, 2004; Chopra, B. *et al.*, 2005; Dattilio, A. and Vizzard, M. A., 2005). Such changes could contribute to pain and hypersensitivity exhibited in these painful syndromes. Because urothelial cells appear to exhibit sensory function, it is possible that plasticity in urothelial receptors is then linked with pain in various bladder syndromes.

Sensitization can be triggered by various mediators (ATP, NO, nerve growth factor (NGF), PGE_2) which may be released by both neuronal and non-neuronal cells (urothelial cells, fibroblasts, mast cells) located near the bladder luminal surface. An important component of the inflammatory response is ATP release from various cell types including urothelium, which can initiate painful sensations by exciting purinergic (P2X) receptors on sensory fibers (Cockayne, D. A. *et al.*, 2000; Burnstock, G., 2001). Recently, it has been shown in sensory neurons that ATP can potentiate the response of vanilloids by lowering the threshold for protons, capsaicin, and heat (Tominaga, M. *et al.*, 2001). This represents a novel mechanism by which large amounts of ATP released from damaged or sensitized cells in response to injury or inflammation may trigger the sensation of pain. These findings have clinical significance and suggest that alterations in afferents or epithelial cells in pelvic viscera may contribute to the sensory abnormalities in a number of pelvic disorders, such as IC, which is consistent with augmented release of ATP in urothelial cells from some patients with IC (Sun, Y. *et al.*, 2001). A comparable disease in cats is termed feline interstitial cystitis (FIC) (Buffington, C. A. *et al.*, 1999; 2001), which is also accompanied by alterations in stretch-evoked release of urothelially derived ATP (Birder, L. *et al.*, 2003).

Though the urothelium maintains a tight barrier to ion and solute flux, a number of factors such as tissue pH, mechanical or chemical trauma, or bacterial infection can modulate this barrier function of the urothelium (Hicks, M., 1975; Anderson, G. *et al.*, 2003). When this function is compromised during injury or inflammation, it can result in the passage of toxic substances into the underlying tissue (neural/muscle layers) resulting in urgency, frequency, and pain during bladder distension. For example, inflammation, injury (spinal cord transection), or IC, all of which increase endogenously generated levels of NO, increase permeability to water/urea in addition to producing ultrastructural changes in the apical layer (Lavelle, J. *et al.*, 2000; Apodaca, G. *et al.*, 2003). Although the mechanism is unknown, these findings may be similar to that in other epithelia where excess production of NO has been linked to changes in epithelial integrity (Han, X. *et al.*, 2004).

Disruption of epithelial integrity may also be due to substances such as antiproliferative factor (APF), which has been shown to be secreted by bladder epithelial cells from IC patients and can inhibit epithelial proliferation thereby adversely affecting barrier function (Keay, S. *et al.*, 1999; 2004).

5.40.3 Potential Clinical Implications: Urothelial Receptors/ Release Mechanisms as Targets for Drug Treatment

It is conceivable that the effectiveness of some agents currently used in the treatment of bladder disorders may involve urothelial receptors and/or release mechanisms. For example, intravesical instillation of vanilloids (capsaicin or resiniferatoxin) improves urodynamic parameters in patients with neurogenic detrusor overactivity and reduces bladder pain in patients with hypersensitivity disorders, presumably by desensitizing bladder nerves (Szallasi, A. and Fowler, C. J., 2002; Kim, J. H. *et al.*, 2003). This treatment could also target TRPV1 on urothelial cells, whereby a persistent activation might lead to receptor desensitization or depletion of urothelial transmitters. Recent studies have demonstrated that intradetrusor injection with botulinum neurotoxin type A (BoNTA) is an effective treatment for bladder hypersensitivity disorders including neurogenic detrusor overactivity (Harper, M. *et al.*, 2004; Reitz, A. and Schurch, B., 2004). Following injection, the toxin binds to bladder cholinergic nerve terminals and cleaves the protein, SNAP25, necessary for exocytosis and release of acetylcholine (Harper M. *et al.*, 2004). There is evidence the BoNTA can suppress the release of a number of mediators (acetylcholine, ATP, and neuropeptides) from both neural and non-neural cells (Morris, J. L. *et al.*, 2001). Suppression of neurotransmitter release from urothelium would serve to blunt afferent activity driven by urothelial-derived release of mediators in a number of lower urinary tract dysfunctions. These findings suggest that urothelial cells exhibit specialized sensory and signaling properties that could allow them to respond to their chemical and physical environments and to engage in reciprocal communication with neighboring urothelial cells as well as nerves within the bladder well. Taken together, pharmacologic interventions aimed at targeting urothelial receptor/ion channel expression or release mechanisms may provide a new strategy for the clinical management of bladder disorders.

Glossary

cyclooxygenase An enzyme–protein complex that catalyzes the production of prostaglandins from arachidonic acid. Cyclooxygenase activity is inhibited by nonsteroidal anti-inflammatory drugs, such as aspirin and ibuprofen.

GIRK G-protein-activated inwardly rectifying potassium channel. A potassium-selective channel that is gated by activated betagamma subunits of Gi/Go G proteins.

Kv channel Voltage-gated potassium channel.

12-lipoxygenase An enzyme that catalyzes the conversion of arachidonic acid to the hydroxyeicosenoic acid (12-HETE) structure.

NSAIDs Nonsteroidal anti-inflammatory drugs. Drugs that inhibit cyclooxygenases and the production of prostaglandins involved in the inflammatory response (e.g., aspirin, ibuprofen, naproxen).

phospholipase A_2 An enzyme that catalyes the formation of arachidonic acid from phospholipids.

5.41.1 The Periaqueductal Gray–Rostral Ventromedial Medulla Pain-Modulating System

The idea that there are well-defined central systems that selectively modulate nociception is usually traced to the demonstration that electrical stimulation in the periaqueductal gray (PAG) region of rats produced potent analgesia. This phenomenon came to be called stimulation-produced analgesia when subsequent work confirmed this finding using quantitative tests of nociception in animals, and when such stimulation was shown to produce clinical analgesia in humans. This was an important advance in documenting that the brain itself could regulate the processing of nociceptive information. Inspired by stimulation-produced analgesia, a significant research effort led to the definition of a brainstem pain modulatory network with critical links in the rostral ventromedial medulla (RVM) as well as the PAG (Figure 1). The antinociception resulting from stimulation in these structures is in large part due to regulation of nociceptive processing at the level of the spinal cord. The PAG–RVM system mediates the analgesic actions of opioids, and it is recruited by internal and environmental challenges. Accumulating evidence from neuroimaging studies supports a role for this system in top-down modulation of pain in humans, such as that produced by placebo or shifts in attention. An overview of descending control, including that mediated by the PAG–RVM system, is provided in Chapter Descending Control Mechanisms. The purpose of this chapter is to review the properties of pain-modulating neurons within the PAG and RVM, and to place this circuitry in a behavioral context.

5.41.1.1 Functional Characterization of the Periaqueductal Gray–Rostral Ventromedial Medulla Pain-Modulating System

The PAG is a cell-rich region surrounding the cerebral aqueduct in the midbrain. The RVM is defined functionally, rather than cytoarchitecturally, and includes the nucleus raphe magnus and adjacent reticular formation. Numerous behavioral studies have demonstrated that nonselective activation of neurons within the PAG or RVM produces a potent antinociception. Activation of PAG–RVM output neurons must mediate this antinociception, as direct excitation of either PAG or RVM neurons produces antinociception and inhibition of noxious-evoked activity of dorsal horn neurons, whereas inactivation of either the PAG or RVM does not. The PAG–RVM modulatory network is also an important substrate for opioid analgesia. Focal application of morphine or mu-opioid agonists at either site is sufficient to produce antinociception comparable to that resulting from systemic morphine administration (see Fields, H. L. *et al.*, 2005 or Heinricher, M. M. and Morgan, M. M., 1999 for reviews).

Along with the evidence that this system mediates the analgesic actions of exogenous and endogenous opioids, the fact that the net behavioral effect of nonselective experimental activation of the PAG or RVM is antinociception led to a general view of the PAG–RVM system as an analgesia system. This system is indeed activated by acute stress and opioid analgesics to inhibit spinal nociceptive processing. However, there is now increasing evidence that the system, especially the

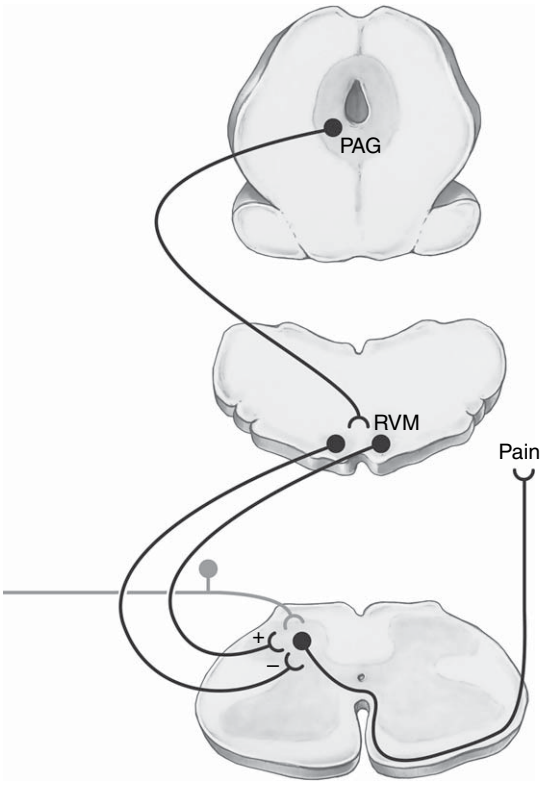

Figure 1 Functional organization of brainstem pain-modulating system with links in midbrain periaqueductal gray (PAG) and rostral ventromedial medulla (RVM). The PAG projects to the RVM. The RVM in turn regulates spinal nociceptive circuitry via a projection through the dorsolateral funiculus to the dorsal horn. This system exerts bidirectional control, and separate populations of RVM neurons mediate descending inhibition and descending facilitation. The PAG is reciprocally linked with forebrain structures including prefrontal cortex, amygdala, and hypothalamus. These substantial interconnections provide an anatomical substrate through which emotional and cognitive variables could influence nociception via the PAG–RVM system.

RVM, also facilitates nociception. The RVM has been implicated in hyperalgesia and allodynia associated with inflammation, nerve injury, acute opioid withdrawal, chronic opioid administration, and the sickness response (see Sections 5.41.2.1 and 5.41.3.2, also Porreca, F. *et al.*, 2002 and Heinricher, M. M. *et al.*, 2003 for recent reviews). The PAG–RVM circuit should therefore be viewed not specifically as an analgesia system, but more generally, as a pain-modulation system. From this perspective, the system has the potential for graded enhancement or inhibition of nociception under different conditions.

5.41.1.2 Pain Modulation as Part of Adaptive Responses to Behavioral and Physiological Challenges

One of the earliest hints that stimulation-produced analgesia was not an experimental curiosity was the demonstration of environmental or stress-induced analgesia. Stress-induced analgesia refers to the fact that any number of situations or experimental procedures that could be characterized as stressful induce behaviorally measurable, and in some cases quite potent, analgesia. For example, stress-induced analgesia can be produced by electric shock, forced swim, and centrifugal rotation as well as biologically relevant threat stimuli such as odors from stressed animals of the same species or exposure to a predator. Analgesia is also elicited as a conditioned response to cues that have been paired previously with noxious or aversive events. This analgesia can be opioid or nonopioid in nature and has been shown by a number of investigators to be mediated by the PAG–RVM system (Bodnar, R. J. *et al.*, 1980; Lewis, J. W. *et al.* 1980; Watkins, L. R. *et al.* 1982; Fanselow, M. S. 1986).

In addition to antinociception, electrical or chemical stimulation of the PAG also evokes autonomic changes commonly associated with cardiovascular aspects of defense, including hypertension (in anesthetized animals) and altered heart rate (Lovick, T. A., 1993; Bandler, R. *et al.*, 2000; Morgan, M. M. and Carrive, P., 2001). Patients in whom deep brain electrodes were implanted in the rostral midbrain/PAG region for relief of intractable pain often found the stimulation to be distinctly disquieting, with reports of a feeling of impending doom or a desire to flee when the stimulation was activated (Nashold, B. S. *et al.*, 1969). Consistent with these reports in humans, rats will work to terminate electrical stimulation in the dorsal PAG (Kiser, R. S. *et al.*, 1978). Moreover, stimulation-produced antinociception in rats is accompanied by species-specific defense behaviors, which include immobility and escape or attack (Bandler, R. and DePaulis, A., 1991; Fanselow, M. S. 1991; Morgan, M. M. and Carrive, P. 2001; Carrive, P. and Morgan, M. M. 2004).

Two factors contributed to the idea that antinociception is recruited as part of defense behaviors: the fact that antinociception is readily evoked by learned or innate danger signals and the observation that stress induces analgesia through activation of the PAG–RVM system. Pain behaviors must sometimes be inhibited in order to give higher precedence to more pressing needs such as escaping from an aggressor or avoiding detection by a predator. However, a more

general view of pain modulation has now developed. Pain inhibition is currently viewed as one component of a number of organized responses that allow an organism to prioritize nociceptive behaviors relative to other internal and external demands. In addition to antinociception, such responses typically include autonomic, endocrine, and motor elements. One example of such an organized defense response would be antinociception as part of preparation for fight or flight when confronted by a predator. Although the circuitry through which the PAG–RVM system is brought into play in response to threat remains to be fully elucidated, inputs from the amygdala and hypothalamus are likely to be critical (Helmstetter, F. J., 1992; Lovick, T. A., 1993; Lumb, B. M. *et al.*, 2002).

There is also evidence that the PAG–RVM system is engaged as part of the response to general immune challenge, as occurs with systemic bacterial infection. Thus, systemic administration of lipopolysaccharide (LPS), a well-accepted model for bacterial infection and sickness, results in changes in nociception mediated at least in part by the RVM (Watkins, L. R. *et al.*, 1994; Romanovsky, A. A. *et al.*, 1996). Just as antinociception is viewed as an adaptive response to external threat, hyperalgesia associated with sickness may promote recuperative behaviors and facilitate healing. As with the defense response to external threat, the system is engaged during sickness to prioritize processing of nociceptive information in accord with other physiological and behavioral goals.

It is likely that the PAG–RVM system also mediates the more subtle shifts in pain processing that occur in the absence of extreme challenge. For example, reflexes or other more highly organized behaviors evoked by noxious stimuli would be expected to interfere with feeding or other homeostatic behaviors. Nociceptive threshold is increased in hungry cats given access to food (Casey, K. L. and Morrow, T. J. 1988; 1989). Moreover, there appears to be an equilibrium between responding to noxious inputs and the need to maintain energy balance. Feeding is suppressed in favor of pain behaviors during the first phase of the formalin response, generally thought to represent a relatively intense sensation. By contrast, pain behaviors are reduced in favor of feeding during the second, less intense, phase of the formalin response (LaGraize, S. C. *et al.*, 2004a). Similarly, paw withdrawal to noxious heat is attenuated during micturition, presumably allowing complete emptying of the bladder without interruption by noxious-evoked movements (Baez, M. A. *et al.* 2005).

Distraction or more global variables such as positive or negative mood also alter pain (see Villemure, C. and Bushnell, M. C., 2002 for a review). Similarly, expectation that a particular manipulation will relieve pain can lead to inhibition of pain (Price, D. D. *et al.*, 1999). Understanding the neural mechanisms through which these and other higher psychological factors modulate pain has been challenging, as these variables are at best difficult to study in nonhuman subjects. Moreover, some modulation of pain perception undoubtedly occurs within thalamocortical circuits. However, imaging studies in humans have now demonstrated that the PAG is activated in placebo and distraction paradigms. There are also changes in activation of this system and associated structures when subjects anticipate pain, and in functional pain disorders (see Tracey, I., in press for a recent review). Studies of opioid-dependent placebo have been most compelling. Petrovic P. *et al.* (2002) found that a placebo procedure (infusion of an inactive vehicle in subjects who had been given the powerful opiate remifentanil in a separate trial) resulted in reduced pain reports and activation of the PAG. This region had previously been activated by the exogenous opiate, suggesting that the placebo manipulation recruited endogenous opioid circuitry within the PAG. Wager T. D. *et al.* (2004) saw similar activation of the anterior cingulate and PAG in a conditioned placebo paradigm. These two studies suggest that recruitment of the PAG contributes to the pain inhibition produced by placebo. Similar studies investigating the effects of attention on pain responses also suggest that activation of the PAG–RVM system contributes to pain suppression when attention is redirected from the noxious stimulus to inputs that have greater behavioral significance (Tracey, I. *et al.*, 2002; Valet, M. *et al.*, 2004). Although correlative, these imaging studies suggest that the PAG–RVM system plays a role in pain modulation produced by placebo, shifts in attention and presumably other cognitive and affective variables.

5.41.2 The Periaqueductal Gray

The PAG comprises heterogeneous cell populations surrounding the cerebral aqueduct. It extends rostrally from the pericoerulear area of the pons to the opening of the third ventricle. As described above, electrical stimulation or focal application of opioids in the PAG produces behaviorally measurable antinociception. However, in addition to pain modulation, it integrates a variety of complex functions, including

cardiovascular and other aspects of defense, general autonomic control, reproductive behaviors, and vocalization (Bandler, R. and Shipley, M. T., 1994).

5.41.2.1 The Periaqueductal Gray and Facilitation of Nociception

The idea that the PAG–RVM system exerts bidirectional control is now well accepted (Porreca, F. *et al.*, 2002; Heinricher, M. M. *et al.*, 2003). Although the focus of functional studies of descending facilitation has been primarily on the RVM (see below, Section 5.41.3.2), there is some evidence that the PAG also contributes to hyperalgesia under some conditions.

First, the PAG contributes to normal levels of responsiveness on the formalin test and to enhanced nociceptive behaviors after foot shock, suggesting a net facilitating output from this region in these paradigms (McLemore, S. *et al.*, 1999; Berrino, L. *et al.*, 2001). Dorsolateral PAG may be important in a generalized sensory sensitization induced by footshock (Crown, E. D. *et al.*, 2004), a facilitation that is recruited in parallel with the well-documented descending inhibition evoked by footshock. Second, focal application of capsaicin or bradykinin into the PAG has a pronociceptive effect (Burdin, T. A. *et al.*, 1992; McGaraughty, S. *et al.*, 2003). Third, prostaglandin release within the PAG apparently recruits descending facilitation, possibly under conditions of inflammation or systemic infection (Vanegas, H. and Tortorici, V. 2002). Thus, cyclooxygenase is constitutively expressed in PAG, and direct microinjection of cyclooxygenase inhibitors in this region reduces responding on cutaneous and visceral nociceptive tests. Moreover, direct application of prostaglandin E_2 in the PAG produces behavioral hyperalgesia and activates RVM neurons that facilitate nociception (Heinricher, M. M. *et al.*, 2004a). Taken together, these findings document the ability of the PAG to facilitate nociception. Consistent with this idea, a recent imaging study demonstrated that stimulation of an area of capsaicin-induced secondary hyperalgesia in human subjects was associated with activation of the PAG (Zambreanu, L. *et al.*, 2005).

5.41.2.2 Afferents to the Periaqueductal Gray

The PAG integrates information from all levels of the central nervous system. The spinal cord sends direct, somatotopically organized projections from the dorsal horn and the intermediate gray to the ventrolateral and lateral PAG (Menetrey, D. *et al.*, 1982; Yezierski, R. P. and Mendez, C. M. 1991). These afferents convey innocuous and noxious information from cutaneous, musculoskeletal, and visceral structures (Wiberg, M. *et al.*, 1987; Yezierski, R. P., 1988; Yezierski, R. P. and Mendez, C. M., 1991; Clement, C. I. *et al.*, 2000). Inputs from the lumbosacral cord arise from a number of regions, including those receiving afferents from pelvic and pudendal nerves (Vanderhorst, V. G. *et al.*, 1996). These latter afferents are proposed to provide important sensory information contributing to PAG functions in sexual behavior and micturition. Approximately half of the spinal input to the PAG is from the upper cervical spinal cord, but the significance of this cervical predominance has not been determined (Vanderhorst, V. G. *et al.*, 2002).

The most substantial afferent inputs to the PAG are from forebrain, including prefrontal and agranular insular cortices as well as the amygdala and hypothalamus (Bandler, R. and Shipley, M. T., 1994; An, X. *et al.*, 1998; Floyd, N. S. *et al.*, 2000). Connections from medial prefrontal cortex are part of a medial prefrontal network associated with visceromotor control through links with the hypothalamus (Ongur, D. and Price, J. L., 2000). Stimulation in the anterior cingulate has been reported by different laboratories to facilitate or suppress nociceptive responses (Hardy, S. G., 1985; Fuchs, P. N. *et al.*, 1996; Calejesan, A. A. *et al.*, 2000). Lesions of the anterior cingulate are generally agreed to reduce nociception in animal models (Pastoriza, L. N. *et al.*, 1996; Donahue, R. R. *et al.*, 2001; LaGraize, S. C. *et al.*, 2004b; in press), consistent with reports in human patients (Foltz, E. L. and Lowell, E. W. 1962; Davis, K. D. *et al.*, 1994; Talbot, J. D. *et al.*, 1995). However, the antinociceptive effect of lesions is presumably due to interference with cortical processing, rather than to activation of descending control. Effects of experimental manipulation of the ventrolateral orbital cortex (VLO) on nociception are similarly complex. Stimulation of the VLO has been reported by one group of investigators to facilitate nociception (Hutchison, W. D. *et al.*, 1996) and another to suppress nociception (Zhang, Y. Q. *et al.*, 1997). The antinociceptive effect of VLO stimulation was blocked by lesion of the PAG, indicating that the connections from this cortex to the PAG are relevant to nociceptive modulation (Zhang, Y. Q. *et al.*, 1997).

Hypothalamic afferents to the PAG are predominantly from the lateral hypothalamus and the anterior hypothalamus/medial preoptic area (MPO)

(Shipley, M. T. *et al.*, 1991; Semenenko, F. M. and Lumb, B. M. 1992; Behbehani, M. M. and Da Costa Gomez, T. M., 1996). At least some of the anterior hypothalamic neurons projecting to the PAG are nociceptive (Lumb, B. M. *et al.*, 2002; Parry, D. M. *et al.*, 2002). The MPO has important roles in autonomic regulation including thermoregulation and fever, as well as in sleep, mating, and maternal behaviors. Electrical stimulation of the MPO produces *c-fos* labeling throughout the PAG (Rizvi, T. A. *et al.*, 1996) and activates PAG–RVM output neurons (Semenenko, F. M. and Lumb, B. M., 1999). Direct application of prostaglandin E_2 in the MPO at low doses produces hyperalgesia that is likely mediated by the PAG–RVM system (Hosoi, M. *et al.*, 1997; Abe, M. *et al.*, 2001; Heinricher, M. M. *et al.*, 2004b).

The central nucleus of the amygdala has massive reciprocal connections with the PAG (Rizvi, T. A. *et al.*, 1991; da Costa Gomez, T. M. and Behbehani, M. M., 1995). The central nucleus receives inputs from the basolateral nucleus, which is a major target of cortical afferents to the amygdala. The central nucleus of the amygdala also receives nociceptive input from the spinal cord, both directly and indirectly via the parabrachial nucleus (Burstein, R. and Potrebic, S., 1993; Gauriau, C. and Bernard, J. F., 2004). PAG neurons respond to stimulation in the amygdala (da Costa Gomez, T. M. *et al.*, 1996), and both stimulation and injection of morphine into the amygdala result in antinociception that is dependent on activation of the descending pathway from PAG to RVM (Pavlovic, Z. W. *et al.*, 1996; Helmstetter, F. J. *et al.*, 1998; McGaraughty, S. and Heinricher, M. M., 2002; 2004).

Afferents to the PAG from the brainstem arise from the medulla, including the RVM. Other brainstem sources of inputs to the PAG include the nucleus tractus solitarius, adjacent nucleus cuneiformis, pontine reticular formation, and the locus coeruleus and other catecholaminergic nuclei (Beitz, A. J., 1982; Herbert, H. and Saper, C. B., 1992).

The strong input to the PAG from forebrain and hypothalamus provides an anatomical substrate through which emotional and cognitive variables could influence pain via the PAG. Information related to motivation and emotion thus converges with direct and indirect visceral and somatic afferent input in the PAG. This convergence is presumably important to pain modulation in allowing the organism to regulate nociceptive processing in accord with current needs and motivational state, particularly in response to environmental or internal challenge.

5.41.2.3 Efferents from the Periaqueductal Gray

The PAG has only a sparse projection to the spinal cord, but a dense projection to the RVM, which in turn projects to the dorsal horn via the dorsolateral funiculus. Inactivation of the RVM prevents the antinociceptive effects of PAG manipulations, indicating that the connection from the PAG to the RVM is the neuroanatomical basis for descending modulation of nociception by the PAG. PAG–RVM projection neurons express neuropeptides, excitatory amino acids, and serotonin. Functional studies implicate excitatory amino acids, serotonin, and endogenous opioids in recruitment of the RVM by the PAG to produce antinociception. A second relay through which the PAG is likely to influence spinal nociceptive processing is pontine catecholaminergic cell groups, as ultrastructural studies demonstrate that these neurons receive inputs from the ventrolateral PAG (see Fields, H. L. *et al.*, 2005 for a recent review).

5.41.2.4 Columnar Organization of the Periaqueductal Gray

Based on both connectivity and function, the PAG has been subdivided into rostrocaudaully oriented columns, designated as dorsomedial (or dorsal), dorsolateral, lateral, and ventrolateral (Carrive, P. and Morgan, M. M., 2004). These columns roughly correspond with subdivisions based on cytoarchitecture that were proposed previously by Beitz A. J. (1985) and Beitz A. J. and Shepard R. D. (1985). Cortical, hypothalamic, and spinal afferents show a preferential distribution to different columns, although there is substantial spread across columnar boundaries (Rizvi, T. A. *et al.*, 1992; An, X. *et al.*, 1998; Floyd, N. S. *et al.*, 2000). Projections to the RVM arise in the dorsomedial, lateral, and ventrolateral columns, but not the dorsolateral column (Abols, I. A. and Basbaum, A. I., 1981; Van Bockstaele, E. J. *et al.*, 1991).

Pain modulation is not constrained by columnar boundaries, and electrical stimulation or microinjection of mu-opioid agonists or neuroexcitant agents throughout the dorsoventral extent of the PAG produces analgesia, particularly at more caudal levels (Waters, A. J. and Lumb, B. M., 1997 Carrive, P. and Morgan, M. M., 2004; Morgan, M. M. and Clayton, C. C. 2005). Antinociception resulting from stimulation in the ventrolateral PAG must be mediated by an endogenous opioid connection, as it is blocked by naloxone. By contrast, the antinociception resulting from

electrical stimulation more dorsally is not mediated by endogenous opioids (Morgan, M. M. 1991).

Antinociception evoked by stimulation of the dorsal and lateral columns is often associated with escape-like behaviors or defensive posturing, hypertension, and tachycardia. By contrast, antinociception produced by stimulation of the ventrolateral PAG is often accompanied by immobility, bradycardia, and in anesthetized animals, hypotension (Depaulis, A. *et al.*, 1994; Morgan, M. M. and Carrive, P., 2001). These findings gave rise to the proposal that the lateral/dorsolateral columns function specifically in active coping, particularly when confronted with an external threat. By contrast, the ventrolateral column was hypothesized to be important in passive coping and recuperation, for example, in response to visceral pain or some other challenge that cannot be controlled or escaped (Keay, K. A. and Bandler, R., 2001).

Two aspects of this framework for PAG organization have been controversial. The first issue is the interpretation of immobility evoked by stimulation in the ventrolateral column. It is not possible to determine from lack of movement alone whether an animal should be viewed as engaging in recuperative behaviors or whether it is instead freezing, that is, exhibiting an active cryptic defense that reduces the likelihood of detection by a predator (Blanchard, R. J. *et al.* 1986; Fanselow, M. S., 1991; Bittencourt, A. S. *et al.*, 2004). The argument that immobility represents passive coping rather than a defensive response is based largely on observations that stimulation in the ventrolateral column in anesthetized animals produce hypotension (Keay, K. A. and Bandler, R., 2001). However, hypotension is not evoked by such stimulation in awake behaving animals (Morgan, M. M. and Carrive, P., 2001). Furthermore, hypotension may not imply a quiescence or recuperative state. For example, although the freezing in a conditioned fear paradigm is associated with hypertension (Carrive, P. 2000), defensive freezing to various threat stimuli can be associated with profound hypotension in various species of wild-trapped rodents (Hofer, M. A., 1970).

A second contentious issue is whether active offensive and escape behaviors should be associated specifically with the lateral/dorsolateral columns, whereas immobility is a function of the ventrolateral column. Immobility as well as escape can be evoked with stimulation of the lateral/dorsolateral columns. Notably, the current needed to induce immobility is lower than that required for active flight behaviors with stimulation in this column (Bittencourt, A. S. *et al.*, 2004). Conversely, bursts of running are often interspersed with periods of inactivity during antinociception evoked from the ventrolateral column (Vianna, D. M. *et al.*, 2001; Morgan, M. M. and Clayton, C. C., 2005). As in the lateral/dorsolateral columns, the current needed to elicit freezing with stimulation in the ventrolateral PAG is lower than that required to elicit jumping (Vianna, D. M. *et al.*, 2001). Moreover, although lesions of the ventrolateral PAG reduce freezing and release running behavior in response to threat (Walker, P. and Carrive, P., 2003, Farook, J. M. *et al.*, 2004), lesions of the dorsolateral PAG have no effect on either freezing or running evoked by exposure to a cat or to a context associated with footshock. In addition, changes in heart rate and activity in this paradigm are seen only when the animal is denied access to a safe hiding place (Dielenberg, R. A. *et al.*, 2004; Farook, J. M. *et al.*, 2004; Leman, S. *et al.*, 2003). Thus, neither active fight or flight behaviors nor immobility appears to be a specific output of a particular column.

These observations suggest that although the idea that the lateral/dorsolateral and ventral columns of the PAG represent centers for active and passive coping has had great heuristic value, a full understanding of the functional significance of the PAG columns is likely to require sophisticated analyses of the neural circuitry of these regions in relevant behavioral paradigms.

5.41.2.5 Intrinsic Circuitry and Neurotransmitters in the Periaqueductal Gray

5.41.2.5.1 Endogenous opioids

All three opioid receptors, mu (MOR), delta (DOR), and kappa (KOR) opioid receptors, are moderately to densely expressed in the PAG (Mansour, A. *et al.*, 1995; Gutstein H. B. *et al.*, 1998; Kalyuzhny, A. E. and Wessendorf, M. W., 1998). The PAG is also rich in endogenous opioids (Mansour, A. *et al.*, 1995). Enkephalin-like immunoreactivity is most dense in the ventrolateral PAG and enkephalin-containing terminals are found apposed to both gamma aminobutyric acid (GABA)ergic and non-GABAergic dendrites, including those of a small percentage of PAG–RVM neurons (Williams, F. G. and Beitz, A. J., 1990). Endomorphin-2 (Tyr-Pro-Phe-Phe-NH_2), an endogenous peptide with high selectivity for the MOR (Zadina, J. E. *et al.*, 1997), is concentrated in the PAG as well as the dorsal horn of the spinal cord (Schreff, M. *et al.*, 1998). Although the endomorphins have a high affinity for the MOR, it appears that these

peptides are only partial agonists for the MOR in the PAG (Narita, M. *et al.*, 2000). Another endogenous opioid found in the PAG is β-endorphin. Discrete populations of β-endorphin-containing neurons in the ventromedial hypothalamus project to the PAG and have been implicated in analgesia produced by electrical stimulation and stress (Millan, M. J., 2002).

MOR agonists produce potent antinociception when applied directly in the PAG (Heinricher, M. M. and Fields, H. L., 2003). The behavioral antinociception produced by these agents is mediated by activation of output neurons projecting to the RVM (Sandkühler, J. and Gebhart, G. F., 1984; Tortorici, V. and Morgan, M. M., 2002). However, as the direct postsynaptic action of MOR agonists on PAG neurons is hyperpolarization (Chieng, B. and Christie, M. J., 1994a; Osborne, P. B. *et al.*, 1996), activation of the output neurons must be via disinhibition. MOR agonists are thought to act presynaptically to block GABAergic inhibition of PAG output neurons. Consistent with this hypothesis, blockade of GABA transmission within the PAG by microinjection of a $GABA_A$ receptor antagonist produces antinociception (Moreau, J. L. and Fields, H. L., 1986; Depaulis, A. *et al.*, 1987). Also consistent with this hypothesis are observations that MOR1 is frequently expressed in GABAergic neurons within the PAG. However, a substantial subset of PAG–RVM projection neurons do express MOR1 (Kalyuzhny, A. E. and Wessendorf, M. W., 1998; Commons, K. G. *et al.*, 2000). These MOR1-positive neurons may target nociceptive facilitating neurons in the RVM (Vanegas, H. *et al.*, 1984; Cheng, Z. F. *et al.*, 1986; Morgan, M. M. *et al.*, 1992;). If so, these MOR1-positive output neurons would be involved in descending facilitation rather than descending inhibition.

Postsynaptic effects of MOR agonists on PAG neurons include hyperpolarization (via activation of a postsynaptic G-protein-activated inwardly rectifying potassium conductance, GIRK) and inhibition of calcium channels (Connor, M. and Christie, M. J., 1998) (Figure 2). MOR agonists also have presynaptic effects, inhibiting GABA and glutamate release from terminals within the ventrolateral PAG (Chieng, B. and Christie, M. J., 1994b; Vaughan, C. W. and Christie, M. J. 1997; Vaughan, C. W. *et al.*, 1997). Presynaptic inhibition of GABAergic neurotransmission is through activation of the arachidonic acid–

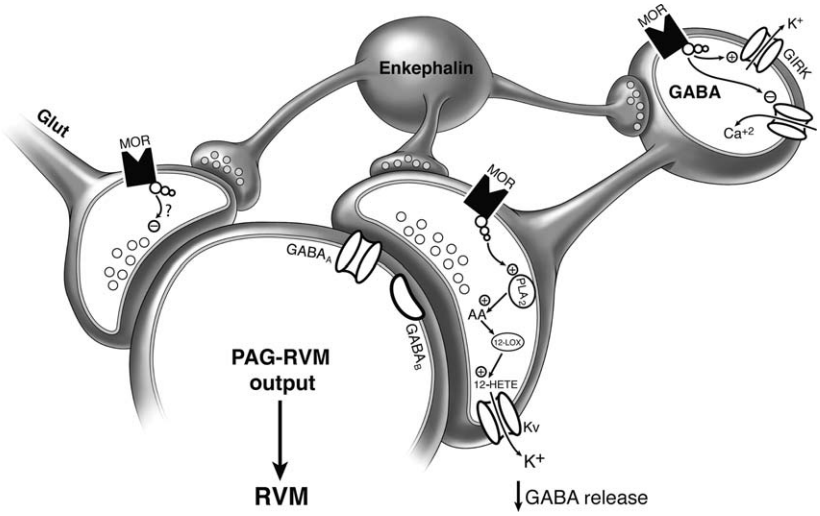

Figure 2 Cellular mechanisms of opioid action within the periaqueductal gray (PAG). Enkephalin-containing synapses are apposed to cell bodies as well as to GABA- and glutamate-containing terminals. The postsynaptic mu-uopoid receptor (MOR) activates G-protein-activated inwardly rectifying potassium channels (GIRKs) and inhibits voltage-gated Ca^{2+} channels to hyperpolarize cells and decrease cell activity. Presynaptic MORs inhibit both GABA and glutamate release on ventrolateral PAG neurons, and apparently use different signal transduction pathways in the terminals. MORs localized to GABA terminals are coupled to voltage-gated potassium channels via activation of the arachidonic acid/12-lipoxygenase (12-LOX) second messenger pathway. Hyperpolarization of the terminal decreases GABA release. The signal transduction pathway for MOR inhibition of glutamate release is currently unknown. MORs are found on GABA containing interneurons in the PAG, as well as on PAG output neurons projecting to the rostral ventromedial medulla (RVM). Activation of the descending antinociceptive pathway by opioids occurs via disinhibition. 12-HETE, 12-hydroxyeicosenoic acid; Kv, voltage-gated potassium; PLA_2, phospholipase A_2.

phospholipase A_2 second messenger pathway. Stimulation of this pathway results in activation of voltage-gated potassium channels (Kv channels) by metabolites of 12-lipoxygenase (Vaughan, C. W. and Christie, M. J., 1997; Vaughan, C. W. *et al.*, 1997). This pathway is independent of adenylyl cyclase, protein kinase A or protein kinase C activity (Vaughan, C. W. *et al.*, 1997). Further research is needed to determine the relevance of the various presynaptic versus postsynaptic opioid actions to the nociceptive modulatory function of the PAG. As already noted, there is good evidence that the behavioral antinociception produced by local application of MOR agonists involves activation of the PAG–RVM output neurons via disinhibition. Whether postsynaptic inhibition or the suppression of glutamatergic transmission plays a role in antinociception is unknown. However, at least in the PAG slice, the effect of presynaptic inhibition of GABAergic transmission apparently predominates, because bath application of the MOR agonist [D-Ala2, N-Met-Phe4, Gly-015] enkephalin (DAMGO) results in activation of neurons that are also directly hyperpolarized by the opioid (Chiou, L. C. and Huang, L. Y., 1999). Thus, under *in vitro* conditions, disinhibition has a relatively large impact, and the net effect of MOR agonist administration is neuronal activation. However, it is not known whether, or under what conditions, endogenous opioids are released to act simultaneously on presynaptic and postsynaptic receptors.

In general, activation of DOR and KORs in the PAG does not result in significant antinociception, at least in rats. A number of groups have found no analgesic effect of microinjection of DOR agonists in the PAG in rats (Bodnar, R. J. *et al.*, 1988; Smith, D. J. *et al.*, 1988; Ossipov, M. H. *et al.*, 1995), although there is one report that microinjection of the $delta_2$ agonist deltorphin into the PAG produces a modest increase in latency of the tail flick response (Rossi, G. C. *et al.*, 1994). KOR agonists are also ineffective in producing analgesia in the PAG (Fang, F. G. *et al.*, 1989). At the cellular level, DOR and KOR agonists have no effect on presynaptic GABA release and in rat do not activate postsynaptic potassium channels (Vaughan, C. W. and Christie, M. J., 1997). However, in mice, KOR agonists inhibit presynaptic GABA release in the PAG, and agonists of all three opioid receptor subtypes activate postsynaptic potassium channels (Vaughan, C. W. *et al.*, 2003). The functions of the three receptors may therefore be different in the two species, and it would obviously be of interest to test the behavioral effects of DOR- and KOR-selective agonists in the PAG in the mouse.

5.41.2.5.1.(i) Opioid/nonsteroidal anti-inflammatory drugs interactions Microinjections of nonsteroidal anti-inflammatory drugs (NSAIDs) into the PAG produce analgesia (Tortorici, V. and Vanegas, H., 1995). This antinociception is apparently mediated at least in part by an endogenous opioid peptide, as the analgesia produced by NSAIDs microinjected into the PAG and RVM is attenuated by the opioid antagonist naloxone (Vanegas, H. and Tortorici, V., 2002).

In addition to stimulating release of endogenous opioids, recent evidence at the cellular level suggests that NSAIDs may also augment the signaling pathway used by opiates, potentiating the actions of exogenous opioids (Figure 3). Coapplication of NSAIDs potentiates the inhibition of GABA release by the MOR partial agonist morphine, although NSAIDs have no effect on GABA release in the absence of morphine (Vaughan, C. W. *et al.*, 1997). NSAIDs primarily inhibit cyclooxygenases (COX-1 and COX-2), one of three types of enzymes (cyclooxygenases, 5-lipoxygenases, and 12-lipoxygenases) that metabolize arachidonic acid. One hypothesis proposed to explain the mechanism of increased analgesia with coapplication of opioids and NSAIDs is that blockade of COX-1 shunts arachidonic acid metabolism through the lipoxygenase pathways to increase the potency of opioid receptor agonists (Vaughan, C. W. *et al.*, 1997; Vaughan, C. W. 1998; Christie, M. J. *et al.*, 1999). The fact that inhibitors of 5-lipoxygenases also appear to potentiate the effects of opioid agonists in the PAG adds further weight to this proposal (Vaughan, C. W. *et al.*, 1997; Christie, M. J. *et al.*, 1999). These results are important in that the combined administration of NSAIDs and opiates may allow lower doses of morphine to be used to provide adequate analgesia while reducing the probability of the development of tolerance and side effects (such as respiratory depression) associated with high doses of opiates. Functional studies of NSAID/opioid interactions in the PAG would therefore be of great interest.

5.41.2.5.1.(ii) Opioid tolerance and dependence The PAG has been implicated in opioid tolerance as well as dependence. Opioid tolerance is the diminished responsiveness to the antinociceptive actions of opioids with chronic administration. Dependence refers to the occurrence of withdrawal signs and/or rebound responses upon removal of the opioid or

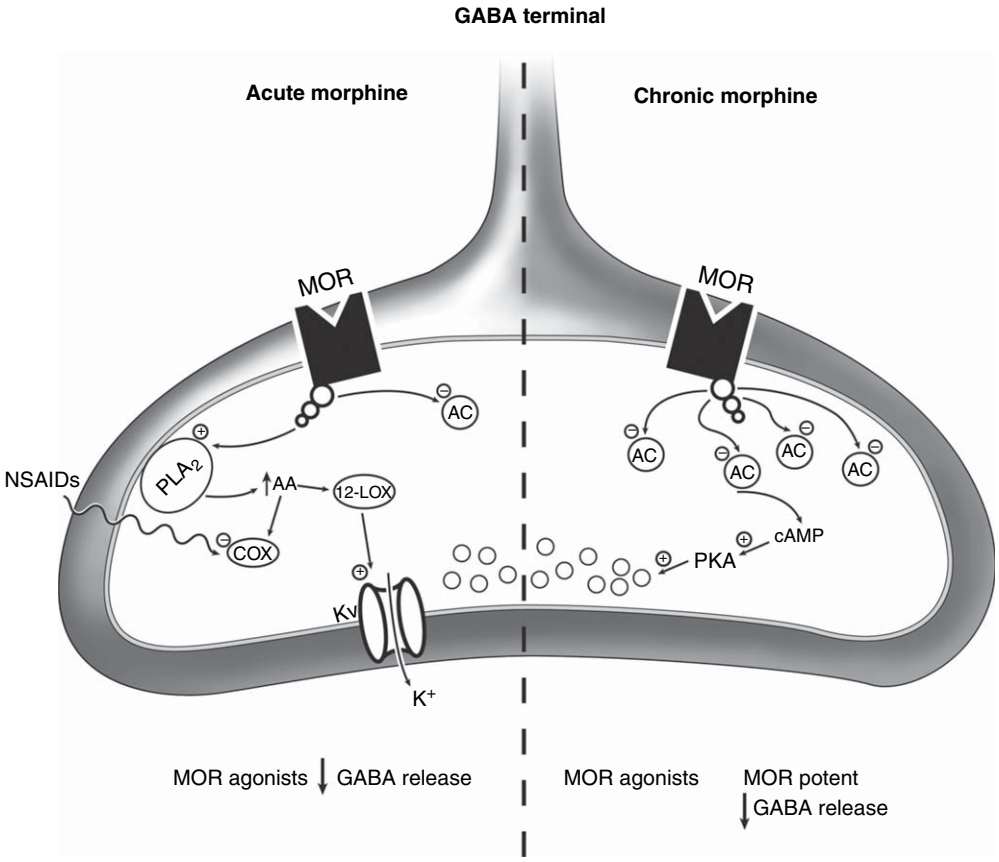

Figure 3 Mu-opioid receptor (MOR) coupling in presynaptic GABA terminals changes with chronic morphine administration. Acute administration of MOR agonists activates MORs coupled to phospholipase A_2 (PLA_2). Activation of PLA_2 increases production of arachidonic acid, which is further metabolized by 12-lipoxygenase (12-LOX). Lipoxygenase metabolites such as 12-HETE activate voltage-gated potassium channels (Kv channels) to hyperpolarize and decrease GABA release from the terminals. Nonsteroidal anti-inflammatory drugs (NSAIDs) potentiate this action of opioids by inhibiting cyclooxygenase (COX)-mediated arachidonic acid metabolism, thereby shunting arachidonic acid to the 12-LOX pathway. Activation of MORs presumably also acutely inhibits adenylyl cyclase (AC) activity in these terminals. Chronic morphine administration upregulates AC and protein kinase A (PKA) activity. After chronic, but not acute, opioid treatment, GABA release is enhanced by increased PKA activity. MOR agonists are more potent inhibitors of this PKA-dependent release, so that opioid removal or blockade of MORs by antagonists results in a rebound increase in GABA release. This increased GABA release may contribute to withdrawal behaviors mediated by the PAG.

administration of an opioid antagonist. Animals exhibit tolerance to the antinociceptive actions of MOR agonists when morphine or MOR agonists are applied directly in the PAG, especially in the caudal ventrolateral aspect (Morgan, M. M. *et al.*, 2005). This tolerance is not due to associative mechanisms, as continuous administration via an implanted pump leads to tolerance in the absence of cues associated with drug administration (Lane, D. A. *et al.*, 2004). The PAG is apparently critical for the development of antinociceptive tolerance when opioids are given systemically because animals chronically treated with morphine microinjected into the PAG display cross-tolerance with morphine given systemically (Jacquet, Y. F. and Lajtha, A., 1976; Siuciak, J. A. and Advokat, C., 1987). Moreover, blockade of PAG opioid receptors using local microinjection of the opioid antagonist naltrexone prevents the development of tolerance to systemically administered morphine (Lane, D. A. *et al.*, 2005). Although RVM neurons lose their responsiveness to PAG morphine administration in tolerant animals (Tortorici, V. *et al.*, 2001), tolerance does not develop as readily when morphine is microinjected into the RVM itself (Morgan, M. M. *et al.*, 2005), and blockade of the RVM does not interfere with the development of tolerance when morphine is applied directly in the PAG (Lane, D. A. *et al.*, 2005). In addition, animals do

not develop behavioral tolerance to direct activation of PAG output neurons that mediate antinociception, for example by microinjecting kainic acid (Morgan, M. M. *et al*., 2003). These latter two findings demonstrate that tolerance is not a result of adaptations downstream from the opioid-sensitive PAG neuron, and indicate that the search for molecular and cellular mechanisms of opioid tolerance should focus on these opioid-sensitive neurons.

The idea that the PAG has a role in opioid dependence derives primarily from observations that blockade of PAG opioid receptors produces a number of withdrawal signs in tolerant animals, and that chronic administration of morphine in the PAG leads to the development of dependence (Bozarth, M. A. 1994). In addition, precipitated withdrawal is associated with increased expression of *c-fos* throughout the PAG, especially in the ventrolateral and lateral aspects (Chieng, B. *et al*., 1995). A substantial number of neurons expressing *c-fos* after precipitated withdrawal are GABAergic (Chieng, B. *et al*., 2005), and neurons positive for *c-fos* do not project to the RVM (Bellchambers, C. E. *et al*., 1998). Thus, as was the case with tolerance, the locus for withdrawal signs in the PAG appears to be upstream from the output neuron projecting to the RVM.

Studies of the membrane properties of PAG neurons following chronic opioid treatment and withdrawal document a host of changes that could contribute to tolerance and/or dependence (Williams, J. T. *et al*., 2001; Bailey, C. P. and Connor, M., 2005). These studies have emphasized altered effects of opioids on GABAergic inhibition and potassium channels. Opioid tolerance is widely assumed to involve a functional uncoupling between opioid receptors and their effectors. The decreased ability of opioids to inhibit the firing of PAG neurons after chronic morphine treatment is consistent with this idea (Bagley E. E. *et al*., 2005; Chieng, B. and Christie, M. D., 1996). However, MOR activation of GIRK channels in PAG is not reduced in animals subjected to repeated intermittent morphine administration that is sufficient to induce antinociceptive tolerance (Ingram, S. L. *et al*., 2007), and the ability of MOR agonists to inhibit GABA release is potentiated rather than reduced in slices from animals treated with chronic morphine. These enhanced actions of MOR agonists are mediated by upregulation of the protein kinase A pathway (Ingram S. L. *et al*., 1998; Hack, S. P. *et al*., 2003). Moreover, recent findings demonstrate that induction of a GABA transporter-mediated cation current in opioid-sensitive neurons in the PAG may be the mechanism of the increased firing rate of these neurons during withdrawal (Bagley, E. E. *et al*., 2005). These latter observations would argue that uncoupling of MOR from pre- or postsynaptic effectors does not underlie antinociceptive tolerance in the PAG. Rather, compensatory mechanisms may mask an underlying increase in the coupling of presynaptic MOR to its effectors that is revealed upon removal of the opioid, leading to withdrawal behaviors. Further work will be needed to bridge the gap between the cellular and behavioral analyses of tolerance and dependence.

5.41.2.5.2 Norepinephrine

The PAG has reciprocal connections with pontomedullary catecholaminergic cell groups (Herbert, H. and Saper, C. B. 1992; Bajic, D. *et al*., 2001). Norepinephrine has multiple effects on PAG neurons that are mediated by α_1- and α_2-adrenergic receptors. Activation of α_1-receptors depolarizes all PAG neurons, whereas α_2-receptor activation hyperpolarizes all neurons, suggesting that both receptors are colocalized on PAG neurons (Vaughan, C. W. *et al*., 1996). However, most neurons preferentially display either a hyperpolarizing or depolarizing response to norepinephrine itself. Neurons in ventrolateral PAG were more likely to be depolarized (~85%), whereas lateral PAG neurons were split equally in exhibiting depolarizing and hyperpolarizing responses. The α_2-mediated hyperpolarization is due to activation of a potassium conductance while the α_1-mediated depolarization depends on inhibition of a potassium conductance and an unidentified norepinephrine-sensitive conductance (Pan, Z. Z. *et al*., 1994; Vaughan, C. W. *et al*., 1996).

The α_2-adrenoceptor agonist clonidine also suppresses GABAergic synaptic transmission, and this suppression is enhanced after chronic morphine treatment (Ingram, S. L. *et al*., 1998). This action of clonidine may be related to its ability to suppress many of the signs of the opioid withdrawal syndrome (Christie, M. J. *et al*., 1997).

5.41.2.5.3 Substance P

NK1 receptors are found in the PAG (Commons, K. G. and Valentino, R. J., 2002), and substance P activates both opioid-sensitive and opioid-insensitive neurons in this region (Ogawa, S. *et al*., 1992; Drew, G. M. *et al*., 2005). In primary afferents and the dorsal horn, substance P has long been associated with nociceptive transmission, and noxious stimulation also increases the release of substance P in the

PAG. This observation would suggest that substance P plays a role in nociceptive transmission in the PAG as in the dorsal horn. However, local morphine administration also increases substance P release in the PAG, and microinjection of exogenous substance P in this region produces significant antinociception (Xin, L. *et al.*, 1997; Rosen, A. *et al.*, 2004). The role of substance P in nociceptive transmission or modulation thus remains to be determined. Substance P has also been implicated in defensive behaviors and aggression, and it produces a conditioned place aversion when microinjected into the dorsolateral PAG (Aguiar, M. S. and Brandao, M. L., 1994). These results point to a more general role for this peptide in defense. Thus substance P may apparently influence a number of functions in the PAG, and functional studies using antagonists are needed to determine the role of endogenous substance P in nociceptive processing and modulation.

5.41.2.5.4 Cannabinoids

Cannabinoids have been used for centuries to provide pain relief (Walker, J. M. and Huang S. M., 2002a) but are of limited utility today because of the significant psychoactive side effects and illegal status in the United States. CB1 receptors are dense throughout the PAG (Herkenham, M. *et al.*, 1991; Tsou, K. *et al.*, 1998). Cannabinoids, like opioids, can mediate antinociception by activating the PAG–RVM descending pathway (see Iversen, L. and Chapman, V., 2002 and Walker, J. M. and Huang, S. M., 2002b for reviews). Endocannabinoids, like endogenous opioids, contribute to the antinociceptive effect of activating the PAG–RVM system (Walker, J. M. *et al.*, 1999; Hough, L. B. *et al.*, 2002), and endocannabinoids in the PAG were recently shown to contribute to stress-induced analgesia (Hohmann, A. G. *et al.*, 2005). Activation of CB1 receptors inhibits both GABA and glutamate release via presynaptic mechanisms. However, cannabinoids have negligible postsynaptic actions on PAG neurons (Vaughan, C. W. *et al.*, 2000).

5.41.3 The Rostral Ventromedial Medulla

5.41.3.1 Connections of the Rostral Ventromedial Medulla

The RVM can be viewed as the brainstem output from the PAG–RVM system, receiving a dense innervation from the PAG and projecting to the dorsal horn through the dorsolateral funiculus. Forebrain structures and the hypothalamus/MPO thus influence the RVM through the PAG, as well as by means of less dense connections directly to the RVM itself. In addition, RVM neurons are likely to receive spinothalamic inputs, either through direct connections to their widespread dendritic arbors or relayed via other brainstem regions such as nucleus reticularis gigantocellularis or the PAG (see Fields, H. L. *et al.*, 2005, for a review.)

In addition to a direct projection to the dorsal horn, the RVM can apparently influence spinal nociceptive processing via catecholamine cell groups in the pons, particularly the A7 cell group. Although there are no noradrenergic neurons within the RVM, antinociception produced by electrical or chemical stimulation in this region is frequently attenuated or blocked by intrathecal administration of noradrenergic antagonists (Hammond, D. L. and Yaksh, T. L., 1984; Proudfit, H. K., 1992). This indicates that part of the antinociceptive effect of RVM stimulation is relayed through one of the descending catecholaminergic pathways, most likely the A7 cell group in the mesopontine tegmentum. The RVM sends connections to the A7 region (Clark, F. M. and Proudfit, H. K., 1991), and these axons originate from a population of neurons distinct from that projecting to the dorsal horn (Buhler, A. V. *et al.*, 2004). This connection to A7 allows the RVM to engage spinally projecting noradrenergic neurons, which would parallel the direct projections from the RVM to the dorsal horn.

The primary outputs from the RVM are thus descending projections to the dorsal horn, both directly and via the mesopontine tegmentum. Ascending connections have also been demonstrated anatomically (Zagon, A. *et al.*, 1994; Hermann, D. M. *et al.*, 1996), but whether these rostral projections play a role in nociceptive modulation is unknown.

5.41.3.2 The Rostral Ventromedial Medulla and Facilitation of Nociception

Although the most robust effect of nonselective experimental activation of the RVM is antinociception, low-intensity electrical stimulation of the RVM and infusions of neuropeptides and *N*-methyl-D-aspartic acid (NMDA) in this region have been shown by various groups to facilitate nociceptive processing (Zhuo, M. and Gebhart, G. F., 1992; Urban, M. O. and Smith, D. J., 1993; Smith, D. J. *et al.*, 1997; Zhuo, M. and Gebhart, G. F., 1997; Kovelowski, C. J. *et al.*, 2000; Friedrich, A. E. and

Gebhart, G. F., 2003; Heinricher, M. M. and Neubert, M. J., 2004; Neubert, M. J. *et al.*, 2004). Inactivation studies demonstrate that hyperalgesia produced by electrical stimulation is not merely an experimental curiosity: lesions implicate the RVM in a variety of models of hyperalgesia and persistent pain, including sickness, acute opiate withdrawal, chronic opioid-induced hyperalgesia, Freund's adjuvant, and mustard oil inflammatory hyperalgesia, following noxious stimulation of a remote body part, and in neuropathic pain models (Kaplan, H. and Fields, H. L., 1991; Morgan, M. M. *et al.*, 1994; Watkins, L. R. *et al.*, 1994; Pertovaara, A. *et al.*, 1996; Ren, K. and Dubner, R., 1996; Urban, M. O. *et al.*, 1996; Mansikka, H. and Pertovaara, A., 1997; Wiertelak, E. P. *et al.*, 1997; Terayama, R. *et al.*, 2000; Porreca, F. *et al.*, 2001; Vanderah, T. W. *et al.*, 2001a; 2001b).

These inactivation studies clearly demonstrate a role for descending facilitation in a variety of enhanced pain states, including inflammation. Nevertheless, there is evidence for an increase in descending inhibition from the RVM during inflammation (Ren, K. and Dubner, R., 2002), with potentiation of the analgesic effectiveness of opioids in the RVM (Hurley, R. W. and Hammond, D. L., 2000; 2001). One intriguing possibility is that inflammation increases the number of RVM neurons expressing MOR (Zhang, L. *et al.*, 2004). Given both the clear demonstration that descending facilitation contributes to the hyperalgesia associated with inflammation and the apparently contradictory evidence for increased descending inhibition, an important question is whether different aspects of nociceptive transmission are differentially affected by inhibition and facilitation during inflammation (Vanegas, H., 2004; Vanegas, H. and Schaible, H.-G., 2004).

5.41.3.3 The Neural Basis for Bidirectional Control from the Rostral Ventromedial Medulla: On- and Off- Cells

5.41.3.3.1 Physiological classification of rostral ventromedial medulla neurons based on reflex-related activity

Initial electrophysiological approaches to the function of the RVM focused on the responses of RVM neurons to noxious stimulation (Anderson, S. D. *et al.*, 1977; Behbehani, M. M. and Pomeroy, S. L., 1978; Guilbaud, G. *et al.*, 1980; Heinricher, M. M. and Rosenfeld, J. P., 1985). In these experiments in deeply anesthetized animals, some neurons were excited, some inhibited, and some unresponsive. The emphasis of most investigators at that time was on the subset of neurons excited by noxious inputs, at least in part because of the idea that pain inhibits pain. However, the notion of recruitment of the pain-inhibiting output from the RVM by noxious stimulation was difficult to reconcile with the observation that noxious-evoked firing of these neurons was suppressed by opioids given in doses thought sufficient to produce analgesia (Anderson, S. D. *et al.*, 1977; Gebhart, G. F., 1982; Heinricher, M. M. and Rosenfeld, J. P., 1985). The on/off/neutral cell classification, introduced by Fields, H. L. *et al.* (1983a), was a significant advance in that it provided a defined framework for hypotheses relating RVM neuronal firing to the pain-modulating function of the region. This approach to RVM physiology was based on the recognition that pain-modulating neurons should discharge in relationship to variables implicated in pain modulation, rather than in response to noxious stimulation. Thus, pain-inhibiting neurons should be activated by analgesic drugs, and during periods of suppressed nociceptive responsiveness, such as that induced by intense stress. Conversely, firing of pain-facilitating neurons should be suppressed during analgesia, and enhanced during hyperalgesia (see Fields, H. M. and Heinricher, M. M., 1985 for an early discussion of the implications of the on/off/neutral cell classification).

In the on/off/neutral cell framework, RVM neurons are recorded in lightly anesthetized rats so that cell firing can be related to changes in nociceptive responding, as measured by spinal nocifensor reflexes. Off-cells are characterized by a cessation of firing during nociceptive reflexes (Figure 4). On-cells are defined by a burst of activity during nociceptive reflexes (Figure 4). Onset of the on-cell reflex-related burst and off-cell pause precede the reflex itself, as well as the thalamic response to the noxious stimulus (Hernandez, N. *et al.*, 1989). Because nociceptive reflexes are generally suppressed when RVM neurons are experimentally activated using electrical stimulation or glutamate microinjection, the fact that off-cell activity ceases abruptly just prior to the execution of nociceptive reflexes suggested that off-cells are the antinociceptive output neurons of the RVM, and that the pause in firing permits responses to occur. Conversely, because on-cells are active during the animal's response to a noxious stimulus, it seemed unlikely that they exert a significant inhibitory effect on nociception. Rather, the reflex-related burst suggested that these neurons have

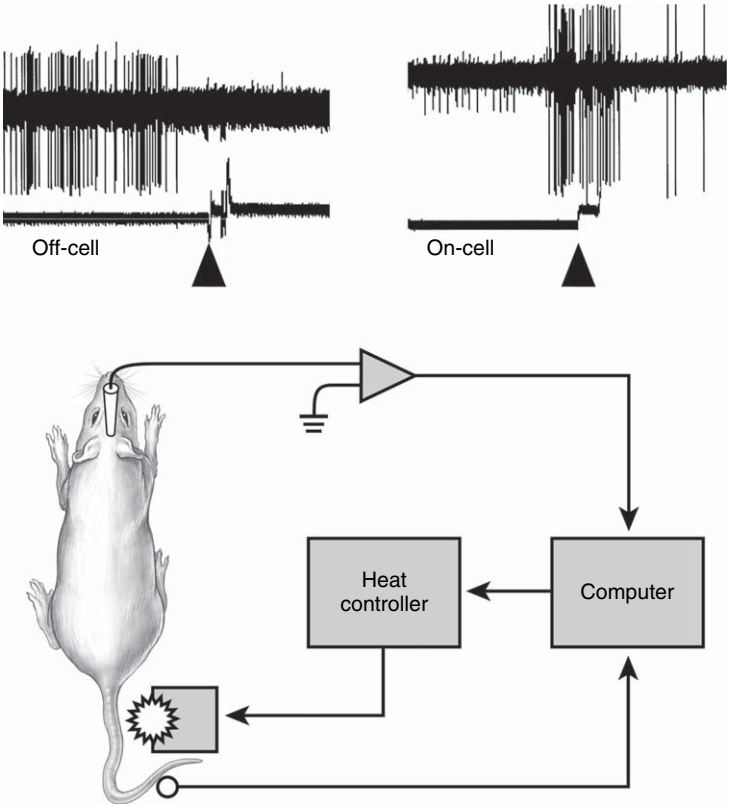

Figure 4 Two cell populations in the rostral ventromedial medulla (RVM), on- and off-cells, explain descending inhibition and facilitation from the RVM. Bottom: Experimental setup shows simultaneous brainstem recording and reflex testing. Top: Single oscilloscope sweeps show activity of a representative off- and on-cell during a tail heat trial. Upper trace is cell discharge, lower trace shows tail position, with arrowhead indicating tail movement. Heat is applied starting at the beginning of the trace. Each trace is 10 s.

a pronociceptive role. Both hypotheses have subsequently received ample confirmation in experiments using selective pharmacological manipulation of the different cell classes (see Section 5.41.3.3.2). At least some cells of both classes project to the dorsal horn (Fields, H. L. *et al.*, 1995).

The remaining cells in the RVM are classified as neutral cells because they show no change in activity associated with nociceptive reflexes. Whether neutral cells have a role in pain modulation remains to be determined (see Section 5.41.3.3.3).

Noxious pinch typically activates on-cells and suppresses off-cell firing. Cutaneous application of mustard oil, which produces an acute inflammation, evokes a strong activation of on-cells and suppresses off-cell firing, leaving neutral cells unaffected (Kincaid, W. *et al.*, in press). Occasional discrepancies between responses to heat and pinch are most likely explained by the fact that the heat-related classification is based on the reflex response evoked by a stimulus at just threshold intensity (Fields, H. L. *et al.*, 1983a; Jinks, S. L. *et al.*, 2004a), whereas pinch stimuli in work published to date have not been limited to withdrawal threshold in intensity, and have not been linked to a withdrawal reflex (Leung, C. G. and Mason, P., 1998; Ellrich, J. *et al.*, 2000; 2001).

On- and off-cell firing is not constant over time. In animals lightly anesthetized with barbiturates, on- and off-cells frequently show alternations between periods of silence and spontaneous discharge. Simultaneous recordings from pairs of on- and off-cells show that excitability within each class varies across the population, but that firing within each class is in phase. Consequently, a subset of either the on- or off-cell class is active at any given time (Barbaro, N. M. *et al.*, 1989), but the two populations are not active simultaneously. By contrast, serotonergic neurons (which can be considered a specific division of neutral cells (Gao, K. *et al.*, 1997; Mason, P., 1997; Gao, K. *et al.*, 1998)) display regular, more or less

constant activity. Nonserotonergic neutral cells vary in their firing, but are often continuously active for prolonged periods. If a withdrawal reflex is evoked when on-cells are in an active period, there is little or no discernible increase in firing (Barbaro N. M. *et al.*, 1986). Because on-cell firing apparently approaches this ceiling during active phases, definitive classification of a neuron as a neutral cell rather than an on-cell requires extensive characterization, with reflex trials delivered during periods of low spontaneous activity. Indeed, Barbaro N. M. *et al.* (1986) noted that earlier work from the Fields group had likely misclassified a number of on-cells as neutral cells.

On-, off-, and neutral cell classes can be identified in awake behaving animals (Oliveras, J. L. *et al.*, 1990; 1991a; 1991b; Leung, C. G. and Mason, P., 1999; Foo, H. and Mason, P., 2005). However, on-cells are more active during waking than sleep, firing in association with the animals' movements. Neurons of this class are also generally more responsive when animals are awake, and more easily activated by innocuous stimulation than when the animals are anesthetized or asleep. Off-cells are more active when the animal is sleeping, and are inhibited in association with movement in awake animals (Leung, C. G. and Mason, P., 1999; Foo, H. and Mason, P., 2005).

5.41.3.3.2 Role of on- and off-cells in pain modulation

Initial functional investigations revealed a number of correlations consistent with the idea that off-cells suppress, while on-cells facilitate, nociception. Both on- and off-cell classes respond to experimental manipulations of the PAG that produce behavioral analgesia (Vanegas, H. *et al.*, 1984; Hutchison, W. D. *et al.*, 1996; Tortorici, V. and Morgan, M. M., 2002). Withdrawal reflexes can generally be elicited at a lower threshold or with shorter latency if on-cells are active and off-cells inactive (Heinricher, M. M. *et al.*, 1989; Ramirez, F. and Vanegas, H., 1989; Bederson, J. B. *et al.*, 1990; Foo, H. and Mason, P., 2003). Antinociception produced by administration of morphine systemically or within the PAG is associated with a uniform activation of off-cells and inhibition of on-cells. Importantly, in animals in which opioid administration fails to produce behavioral analgesia, changes in cell firing are inconsistent. Thus, changes in on- and off-cell firing are related to antinociception rather than to opioid administration as such (Fields, H. L. *et al.*, 1983b; Cheng, Z. F. *et al.*, 1986.). Reduced nociceptive thresholds in acute opioid withdrawal and secondary hyperalgesia during noxious stimulation of a distant body region are correlated with on-cell activation (Bederson, J. B. *et al.*, 1990; Morgan, M. M. and Fields, H. L., 1994). On-cells also facilitate escape responses to intense noxious stimulation, and probably contribute to secondary hyperalgesia during acute inflammation (Jinks, S. L. *et al.*, 2004b; Kincaid, W. *et al.*, in press). Finally, on-cells have been implicated in hyperalgesia associated with the sickness response. Hyperalgesia produced by systemic administration of bacterial endotoxin is blocked by lesion of the RVM (Watkins, L. R. *et al.*, 1994; Wiertelak, E. P. *et al.*, 1997). Although on-cells have not been studied in animals challenged with endotoxin, these neurons are activated by direct administration of prostaglandin E_2 in the MPO (Heinricher, M. M. *et al.*, 2004b), which can be considered a model for central components of the sickness response (Oka, T. *et al.*, 1994; Hosoi, M. *et al.*, 1997).

The obvious limitation of these observations is that they are correlative. The RVM plays an important role in a number of functions other than pain modulation, and many neurons in this region are known to exhibit correlations with various physiological parameters including EEG, blood pressure, and body temperature. Causal inferences relating on- or off-cell discharge to altered nociceptive processing thus require selective experimental manipulation of each cell class as a whole, for example, by microinjection of drugs that differentially alter the firing of the different classes. If altered firing of a particular class leads to modified nociceptive responses, one can conclude that the observed change in cell activity mediated the resulting change in behavior.

A series of studies using the above approach of manipulating RVM circuitry directly have demonstrated that activation of off-cells is sufficient to produce analgesia, and required for the antinociceptive actions of systemically administered morphine (Heinricher, M. M. and Tortorici, V., 1994; Heinricher, M. M. *et al.*, 1994; 1997; 1999; 2001a; 2001b; Meng, I. D. and Johansen, J. P., 2004; Neubert, M. J. *et al.*, 2004; Meng, I. D. *et al.*, 2005). Similar approaches have recently been extended to testing the effects of off-cell activation. Such studies show that on-cells do not contribute significantly to nociceptive threshold under basal conditions as suppression of the reflex-related firing of on-cells does not by itself reduce responding (Heinricher, M. M. and McGaraughty, S., 1998; Meng, I. D. *et al.*, 2005). However, direct activation of on-cells has a pronociceptive effect: microinjection of neurotensin or cholecystokinin (CCK) at doses that activate on-cells

selectively produces thermal hyperalgesia (Heinricher, M. M. and Neubert, M. J., 2004; Neubert, M. J. *et al.*, 2004). Activation of on-cells by CCK likely contributes to nerve injury pain (Kovelowski, C. J. *et al.*, 2000; Porreca, F. *et al.*, 2001; Burgess, S. E. *et al.*, 2002). Microinjection of a CCK-2 receptor antagonist in the RVM also interferes with the paradoxical hyperalgesia associated with prolonged opioid administration (Xie, J. Y. *et al.* 2005), indicating that CCK-mediated activation of on-cells is also involved in this phenomenon. Viewed collectively, the above data provide strong evidence that off-cells suppress nociception, and that on-cells facilitate nociception. The balance of activity between the on- and off-cell populations therefore allows graded bidirectional control of nociceptive responding (Figure 5).

Functional studies demonstrate that the RVM exerts bidirectional control over visceral, as well as cutaneous, hyperalgesia (Coutinho, S. V. *et al.*, 1998). The behavioral response to colorectal distension is suppressed by microinjection of morphine in the RVM (Friedrich, A. E. and Gebhart, G. F., 2003), which is known to activate off-cells (Heinricher, M. M. *et al.*, 1994). Conversely, microinjection of CCK, at a dose that likely activates on-cells (Heinricher, M. M. and Neubert, M. J., 2004), enhances the behavioral response to colorectal distension (Friedrich, A. E. and Gebhart, G. F., 2003). Thus, on- and off-cells appear to modulate behavioral responses evoked by colorectal distension just as they modulate responses evoked by cutaneous heat. The lack of congruence between visceral inputs to RVM neurons and heat-evoked reflex-related responses of these neurons (Brink, T. S. and Mason, P., 2004) may be related to the inhibitory effect of colorectal distension on sensory processing of cutaneous stimuli (Bouhassira, D. *et al.*, 1994; 1998; Pertovaara, A. and Kalmari, J., 2002; Kalmari, J. and Pertovaara, A., 2004). More generally, a difference in on- and off-cell firing associated with cutaneous versus visceral noxious-evoked reflexes emphasizes the basic principle that the functions of RVM neurons must be inferred from their outputs (i.e., from the behavioral or physiological effect of selective manipulation of the difference cell classes), rather from inputs.

5.41.3.3.3 Role of neutral cells

All cells that are not classified as on- or off-cells are grouped together under the heading of neutral cells. Whether these neurons have any role in pain modulation has long been an important question. By definition, the firing of neutral cells is unchanged during behavioral responses to noxious stimulation, and neutral cell firing is also unaffected by MOR or DOR agonists, norepinephrine, neurotensin, or CCK, all of which alter firing of on- and/or off-cells and nociceptive behavior when applied in the RVM (Heinricher, M. M. *et al.*, 1994; 1988; Harasawa, I. *et al.*, 2000; Heinricher, M. M. *et al.*, 2001a; Neubert, M. J., *et al.*, 2004). KOR agonists depress the firing of some neutral cells, but the functional implications of this depression have not been explored (Meng, I. D. *et al.*, 2005). The differential pharmacology of neutral cells supports their categorization as distinct from on- and off-cells. Neutral cells, or subpopulations of neutral cells, might be involved in some other functions of the RVM, for example thermoregulation (Nakamura, K. *et al.*, 2002; Madden, C. J. and Morrison, S. F., 2003).

Despite the lack of direct evidence that neutral cells have a role in pain modulation, interest in this cell class remains high. This is in part because a subset of neutral cells contains serotonin (Potrebic, S. B. *et al.*, 1994; Mason, P., 2001), and serotonin is implicated in descending facilitation as well as descending inhibition of nociception (Le Bars, D., 1988; Calejesan, A. A. *et al.*, 2000; Suzuki, R. *et al.*, 2004). However, there is significant controversy as to

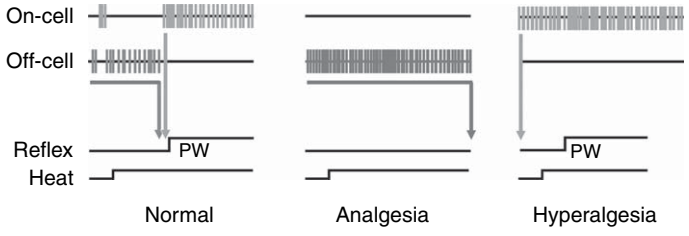

Figure 5 Balance of activity between on- and off-cell populations allows graded bidirectional control of nociceptive responding. *Left column, normal conditions*: Application of heat (arrow) to a rat's tail or paw evokes a paw withdrawal reflex. The off-cell pauses and on-cell becomes active just before the reflex occurs. *Middle column*, *analgesia*: Manipulations that cause off-cells to become continuously active also suppress on-cell firing and application of heat does not evoke a response. *Right column, hyperalgesia*: Reflexes occur with a shorter latency if heat is applied during a period when on-cells are activated (for example, as a consequence of a prior noxious stimulus).

the exact role of serotonergic neutral cells in pain modulation. Immunohistochemically identified serotonergic neurons express MOR, DOR, and KOR (Kalyuzhny, A. E. and Wessendorf, M. W., 1999; Wang, H. and Wessendorf, M.W., 1999; Marinelli, S. *et al.*, 2002). However, neutral cells, including putative serotonergic neutral cells, as a class do not respond to morphine or MOR agonists given systemically or microinjected into the RVM (Barbaro, N. M. *et al.*, 1986; Heinricher, M. M. *et al.*, 1994; Gao, K. *et al.*, 1998). Why neurons that express the MOR fail to respond to MOR agonists remains an important puzzle. A similar mismatch between *in vivo* functional data and immunohistochemical data arises with the neurotensin receptor. Some immunohistochemically identified serotonergic neurons express neurotensin receptor-like immunoreactivity (NT1-ir), and behavioral studies show that microinjection of high doses of neurotensin or a NT1 agonist produce antinociception (Smith, D. J. *et al.*, 1997; Neubert, M. J. *et al.*, 2004; Buhler, A. V. *et al.* 2005). However, physiologically identified neutral cells do not respond to neurotensin when microinjected into the RVM at a dose sufficient to produce behavioral antinociception (Neubert, M. J. *et al.*, 2004). Again, there is no obvious explanation for why neurons expressing the NT1 receptor show no change in firing following microinjection of neurotensin. Resolution of these discrepancies between immunohistochemical and electrophysiological findings will require immunohistochemical labeling of functionally identified neurons.

A second reason for continued interest in neutral cells is the report that the response properties of many neutral cells change to those of on- or off-cells over the course of hours during prolonged inflammation (Miki, K. *et al.*, 2002). A subset of neutral cells may therefore be involved in long-term facilitation or inhibition of nociception, or in other changes in behavior or physiology during inflammation. As discussed above however, the pharmacology of such cells would presumably differ from cells classified as on- or off-cells in the absence of inflammation.

5.41.3.4 Pharmacology of Nociceptive Modulation in the Rostral Ventromedial Medulla

Among the neuropeptides and neurotransmitters found in RVM neurons are serotonin, substance P, enkephalin, thyrotropin-releasing hormone, galanin, somatostatin, CCK, GABA, and acetylcholine (Bowker, R. M. *et al.*, 1983; Mantyh, P. W. and Hunt, S. P., 1984; Menetrey, D. and Basbaum, A. I., 1987; Millhorn, D. E. *et al.*, 1987a; 1987b; Bowker, R. M. and Abbott, L. C., 1988; Millhorn, D. E. *et al.*, 1989; Palkovits, M. and Horvath, S., 1994; Skinner, K. *et al.*, 1997). With the exception of serotonin (see above, Section 5.41.3.3.1), the relationship between physiological/functional class (on-, off-, and neutral cell classification) and expression of different neurotransmitters has yet to be examined.

5.41.3.4.1 Gamma-aminobutyric acid and glutamate: the off-cell pause and on-cell burst

One approach to identifying the neurotransmitter (s) mediating defined synaptic inputs is to attempt to block those inputs using iontophoretic application of neurotransmitter antagonists (Hicks, T. P., 1983). Iontophoresis of $GABA_A$ receptor antagonists selectively blocks the off-cell pause, demonstrating that this reflex-related inhibition of off-cell firing is mediated by GABA (Heinricher, M. M. *et al.*, 1991). Consistent with the idea that the off-cell pause removes descending inhibition and permits noxious information to be processed, microinjection of $GABA_A$ receptor antagonists in the RVM blocks the off-cell pause and produces behavioral antinociception (Drower, E. J. and Hammond, D. L., 1988; Heinricher, M. M. and Kaplan, H. J. 1991; Heinricher, M. M. and Tortorici, V., 1994; Gilbert, A. K. and Franklin, K. B., 2001). Interestingly, Nason M. W., Jr. and Mason P. (2004) recently suggested that the effect of RVM GABA receptor antagonism is selective for stimulation of the tail, with facilitation rather than inhibition of responses evoked by stimulation of the foot. However, this is difficult to reconcile with the antinociception observed by others using the hot plate and formalin tests, as both of these tests involve stimulation of the hindpaw (Gilbert, A. K. and Franklin, K. B., 2001). The source of GABAergic input to off-cells is unknown, but it is presumed to be the target of MOR agonists (see Section 5.41.3.4.2).

Although firing of both on-cells and neutral cells is inhibited by iontophoretically applied GABA, neither cell class displays significant disinhibition during iontophoresis of $GABA_A$ receptor antagonists. This observation implies that on-cells and neutral cells express GABA receptors, but that there is little ongoing GABAergic control of their firing, at least in the lightly anesthetized rat (Heinricher, M. M. *et al.*, 1991).

Iontophoretic application of excitatory amino acids excites all three classes of RVM neurons. However, antagonist studies specifically implicate excitatory amino acid transmitters in reflex-related activation of on-cells and opioid-induced activation of off-cells. Thus, iontophoretic application of the broad-spectrum excitatory amino acid antagonist kynurenate blocks the reflex-related on-cell burst, without affecting the activity of off-cells or neutral cells (Heinricher, M. M. and Roychowdhury, R., 1997). Kynurenate microinjected into the RVM at a dose that blocks on-cell activation does not result in increased withdrawal latency to noxious heat, indicating that the on-cell burst does not control nociceptive threshold, at least under normal conditions (Heinricher, M. M. and McGaraughty, S., 1998). However, it is possible that the firing of on-cells during and after the withdrawal modulates the magnitude or force of the reflex, or primes responses to subsequent stimuli (Ramirez, F. and Vanegas, H., 1989; Jinks, S. L. *et al.*, 2004b).

A second important role for excitatory amino acid transmission in the RVM is the recruitment of off-cells by opioids (Heinricher, M. M. *et al.*, 2001b). Disinhibition of off-cells leads to NMDA-mediated activation of these neurons, amplifying the effect of disinhibition (see the next Section 5.41.3.4.2).

5.41.3.4.2 Opioid actions in the rostral ventromedial medulla

All three opioid receptors, MOR, DOR, and KOR, are found in the RVM, although their expression is much less dense than in the PAG (Gutstein H. B. *et al.*, 1998; Kalyuzhny, A. E. *et al.*, 1996; Wang, H. and Wessendorf, M. W., 1999). The RVM, and specifically activation of off-cells, is required for the analgesic actions of systemically administered morphine (Dickenson, A. H. *et al.*, 1979; Azami, J. *et al.*, 1982; Mitchell, J. M. *et al.*, 1998; Heinricher, M. M. *et al.*, 2001a; 2001b; Gilbert, A. and Franklin, K., 2002). Like the PAG, the RVM supports MOR-mediated analgesia. Thus, direct local microinjection of morphine or MOR agonists in the RVM produces an antinociception equivalent to that produced by systemic morphine administration (Heinricher, M. M. and Morgan, M. M., 1999). Moreover, PAG and RVM interact in a synergistic fashion (Rossi, G. C. *et al.*, 1994). This is at least in part because exogenous opioid administration at one site recruits endogenous opioid mechanisms at the other. Thus, microinjection of morphine in the PAG apparently evokes release of endogenous opioids in the RVM (Kiefel, J. M. *et al.*, 1993; Pan, Z. Z. and Fields, H. L., 1996; Roychowdhury, S. M. and Fields, H. L., 1996) to produce its antinociceptive effect.

The local actions of MOR agonists within the RVM are well understood at both the cellular and circuit levels. On-cells are directly inhibited by MOR agonists. Neither neutral cells nor off-cells are directly sensitive to MOR agonists, but off-cells are activated indirectly, most likely via disinhibition (Figure 6). Microinjection of MOR agonists in the RVM suppresses on-cell firing and activates off-cells, resulting in behavioral antinociception (Heinricher, M. M. *et al.*, 1992; 1994). The activation of off-cells is required for the antinociceptive effect (Heinricher, M. M. *et al.*, 1997). Suppression of on-cell firing is not necessary for RVM-mediated analgesia (Heinricher, M. M. *et al.*, 1994; Neubert, M. J. *et al.*, 2004), although it likely contributes. Selective inhibition of on-cell firing reduces the force, although not the latency, of withdrawal to noxious heat (Heinricher, M. M. and McGaraughty, S., 1998; Jinks, S. L. *et al.*, 2004b).

Studies at the cellular level reveal that some neurons are inhibited directly by MOR agonists, whereas others are disinhibited via presynaptic inhibition of GABAergic transmission (Pan, Z. Z. *et al.*, 1990). These findings are thus consistent with the direct inhibition of on-cells and indirect activation of off-cells observed *in vivo*. RVM neurons studied *in vitro* are classified as secondary cells, which are directly

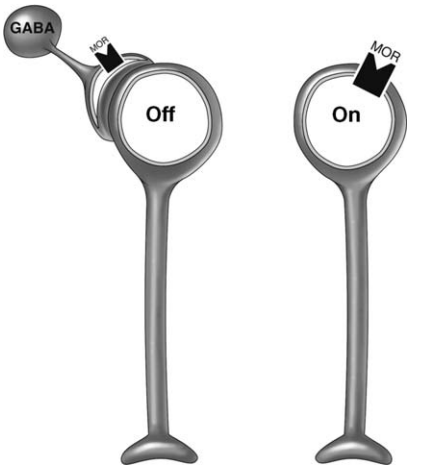

Figure 6 Disinhibition of off-cells, direct inhibition of on-cells mediates opioid analgesia. On-cells are inhibited, directly, by morphine and mu-opioid receptor (MOR) agonists. Off-cells are not inhibited by MOR agonists, but are activated, via disinhibition. MORs are thus presumed to be located on on-cells, and on gamma aminobutyric acid (GABA)ergic inputs to off-cells.

inhibited by MOR agonists, and primary cells, which are not. Primary cells do however receive opioid-sensitive GABAergic inputs, and are disinhibited by MOR agonists (Pan, Z. Z. *et al.*, 1990). Secondary cells presumably map to on-cells recorded *in vivo*, and primary cells to off-cells and neutral cells identified *in vivo*.

5.41.3.4.2.(i) Delta opioid receptor Like MOR agonists, DOR agonists, particularly $delta_2$ agonists, produce behavioral hypoalgesia when microinjected into the RVM. The effects of $delta_1$ agonists are less robust than those of $delta_2$ agonists (see Heinricher, M. M. and Fields, H. L., 2003 for review of the role of the DOR in pain modulation in the RVM). *In vitro*, the DOR agonists deltorphin and [D-Pen2, D-Pen5] enkephalin (DPDPE) elicit hyperpolarizing currents in a substantial minority of RVM neurons (Marinelli S. *et al.*, 2005). Some, but not all, of these neurons were also hyperpolarized by MOR agonists. It thus appears that a subset of DOR-sensitive RVM neurons falls into the secondary cell category. In experiments *in vivo*, microinjection of deltorphin into the RVM increases the latency and reduces the amplitude of the reflex-related on-cell burst, reduces the duration of the reflex-related off-cell pause, and evokes a small but statistically significant increase in tail flick latency (Harasawa, I. *et al.*, 2000).

Molecular, cellular, and behavioral approaches point to interactions between MOR- and DOR-mediated processes, but experiments designed to uncover such interactions within the RVM reveal that the effects of MOR and DOR agonists in the RVM are independent under basal conditions (Hurley, R. W. and Hammond, D. L. 2001; Kalra, A. *et al.*, 2001). However, there is a time-dependent recruitment of supraspinal DOR function in inflammation, so that DOR agonists microinjected into the RVM are more effective in animals subjected to long-lasting inflammation compared to noninflamed controls. MOR agonists are also more potent in these animals (Hurley, R. W. and Hammond, D. L., 2000; 2001). This increased opioid action may reflect an increase in the release of endogenous opioids acting at the DOR (Williams F. G. *et al.*, 1995) and/or translocation of DOR from the cytoplasm to the plasma membrane (Commons, K. G. *et al.*, 2001; Commons, K. G., 2003). Coexpression of MOR and DOR on individual RVM neurons may also play a role (Marinelli, S. *et al.*, 2005).

5.41.3.4.2.(ii) Kappa opioid receptor The role of the KOR in the pain-modulating functions of the RVM remains controversial. Electrophysiological studies in the RVM slice demonstrate pre- and post-synaptic effects of KOR agonists in the RVM. However, it is unclear whether neurons in which KOR agonists evoke an outward current are a separate population from those inhibited by MOR agonists (Pan, Z. Z. *et al.*, 1997; Ackley, M. A. *et al.*, 2001; Marinelli, S. *et al.*, 2002; Bie, B. and Pan, Z. Z., 2003). Microinjection of a KOR agonist into the RVM has been reported to either have no behavioral effect (Pan, Z. *et al.*, 2000; Meng, I. D. *et al.*, 2005) or to produce antinociception, depending on the nociceptive test as well as the sex of the animal (Tershner, S. A. *et al.*, 2000; Ackley, M. A. *et al.*, 2001). KOR agonists also block the antinociceptive effect of PAG microinjection of a MOR agonist or systemic morphine administration (Pan, Z. *et al.*, 2000; Bie, B. and Pan, Z. Z., 2003; Meng, I. D. *et al.*, 2005) as well as MOR-mediated conditioned hypoalgesia (Foo, H. and Helmstetter F. J., 2000). This antianalgesic effect of the KOR agonist is presumably due to a blockade of off-cell activation (Bie, B. and Pan, Z. Z., 2003; Meng, I. D *et al.*, 2005). KOR agonists can also block hyperalgesia when microinjected into the RVM, presumably via presynaptic blockade of excitatory inputs to on-cells (Ackley, M. A. *et al.*, 2001; Meng, I. D. *et al.*, 2005).

5.41.3.4.3 Norepinephrine

As with the KOR, norepinephrine likely influences both the nociceptive facilitating and inhibiting outputs from the RVM. Behavioral studies have reported that blockade of α_1-adrenergic receptors produces antinociception (Sagen, J. and Proudfit, H. K., 1981) and reduces hyperalgesia associated with acute opioid withdrawal (Bie, B. *et al.*, 2003). Agonists at the α_1 receptor produce hyperalgesia and conditioned place avoidance, and the increased nociception is dissociated from the negative affective state in these animals (Hirakawa, N. *et al.*, 2000).

Surprisingly, α_2 agonists have been reported to produce analgesia (Sagen, J. and Proudfit, H. K., 1985; Haws, C. W. *et al.*, 1990) as well as to block opioid analgesia (Bie, B. *et al.*, 2003) when microinjected into the RVM. The neural basis for these conflicting results is unclear, as electrophysiological studies are also inconsistent. *In vivo*, iontophoretically applied norepinephrine and α_2 agonists suppress the firing of on-cells, whilst α_1 agonists activate on-cells. Off-cells and neutral cells do not respond to

iontophoretically applied norepinephrine or adrenergic agents (Heinricher, M. M. *et al.*, 1988). By contrast, in experiments in the RVM slice, α_2 agonists hyperpolarize primary cells (presumably off-cells and/or neutral cells), and α_1 agonists activate all cells (Bie, B. *et al.*, 2003). The findings from the *in vivo* study are thus more consistent with an antinociceptive effect of α_2 receptor activation, whereas the studies in the slice are more consistent with the antiopioid action of these agents.

5.41.3.4.4 Cannabinoids

As noted above (Section 5.41.2.5.4), the PAG–RVM system is now recognized to mediate at least part of the antinociceptive effect of cannabinoids. The RVM is required for the antinociceptive action of systemically administered cannabinoid agonists (Meng, I. D. *et al.*, 1998), and microinjection of CB1 agonists into the RVM produces moderate antinociception (Martin, W. J. *et al.*, 1998; Monhemius, R. *et al.*, 2001; Meng, I. D. and Johansen, J. P., 2004). Off-cells display a measurable increase in activity after local infusion of a CB1 agonist in the RVM, and the reflex-related activity of on-cells is significantly reduced (Meng, I. D. and Johansen, J. P., 2004). Both of these effects are presumed to reflect a presynaptic action, as cannabinoids block excitatory and inhibitory synaptic currents, but have negligible postsynaptic effects in RVM (Vaughan C. W. *et al.*, 1999).

5.41.3.4.5 Cholecystokinin

Endogenous CCK has long been recognized to counter opioid analgesia and to contribute to enhanced nociception, particularly in neuropathic pain states (Stanfa, L. *et al.*, 1994; Wiesenfeld-Hallin, Z. *et al.*, 1999). In humans, CCK antagonism increases the analgesic actions of morphine and placebo (Price, D. D. *et al.*, 1985; Benedetti, F. and Amanzio, M., 1997; McCleane, G. J., 1998). CCK is found in the RVM (Skinner, K. *et al.*, 1997), and has both pronociceptive and antiopioid actions in this region. CCK in the RVM is implicated in the expression of allodynia and thermal hyperalgesia in the spinal nerve ligation model of nerve injury pain as well as in hyperalgesia associated with chronic morphine administration (Kovelowski, C. J. *et al.*, 2000; Xie, J. Y. *et al.*, 2005). Furthermore, focal application of relatively high doses of exogenous CCK in the RVM produces cutaneous and visceral hyperalgesia (Kovelowski, C. J. *et al.*, 2000; Friedrich, A. E. and Gebhart, G. F., 2003; Heinricher, M. M. and Neubert, M. J., 2004). Notably, CCK activates on-cells selectively when microinjected in a dose sufficient to produce behavioral hyperalgesia. This points to on-cells as critical mediators of CCK hyperalgesia in the RVM (Heinricher, M. M. and Neubert, M. J., 2004).

CCK also has antiopioid actions in the RVM, albeit through a different mechanism than that through which it produces hyperalgesia. Focal application of a low dose of CCK in the RVM attenuates both opioid activation of off-cells and opioid-induced antinociception without affecting baseline nociceptive responding or the activity of on-cells (Heinricher, M. M. *et al.*, 2001a). The signal transduction mechanisms that underlie this antiopioid action of CCK are unknown. In the hippocampus, CCK reduces opioid-induced disinhibition by increasing GABA release (Miller, K. K. *et al.*, 1997), raising the possibility that CCK acts presynaptically to block disinhibition of off-cells in the RVM.

5.41.3.4.6 Neurotensin

Like CCK, neurotensin has multiple effects in the RVM. Microinjection of this peptide within the RVM gives rise to a dose-related, bidirectional effect on nociceptive behaviors (tail flick, hot plate, and visceromotor responses to colorectal distension) and dorsal horn nociceptive neurons. Extremely low doses produce facilitation, whereas high doses produce antinociception. Intermediate doses are without effect (Urban, M. O. and Smith, D. J., 1993; Smith, D. J. *et al.*, 1997; Urban, M. O. and Gebhart, G. F., 1997; Urban, M. O. *et al.*, 1999; Neubert, M. J. *et al.*, 2004.). Behavioral hyperalgesia is mediated by selective activation of on-cells, whereas the hypoalgesia produced by higher doses is due to recruitment of off-cells. Neutral cells do not respond to neurotensin at any dose (Neubert, M. J. *et al.* 2004).

5.41.3.4.7 Nociceptin/orphanin FQ

The identification of an opioid-like receptor (ORL-1) that did not bind classical opioid peptides suggested that additional peptides might exist that could modulate nociception. However, despite its structural and functional similarities to the opioid receptors, activation of ORL-1 by its endogenous ligand, referred to as nociceptin or orphanin FQ (OFQ), does not produce antinociception when applied within the RVM. Rather nociceptin/OFQ potently inhibits all neurons in the RVM. As a consequence, focal application of nociception/OFQ in the RVM is effectively a functional lesion of the

region, and interferes with both antinociceptive and pronociceptive outputs (see Heinricher, M. M., in press for a review).

5.41.3.5 Physiological Activation of Nociceptive Modulatory Neurons in the Rostral Ventromedial Medulla

Given a pronociceptive role for on-cells and an antinociceptive role for off-cells, the obvious question that arises is how and when these two classes of neurons with opposing functions are recruited to modulate nociception. This question remains a significant challenge, in part because a number of factors likely to influence nociception via the RVM involve higher-order neural structures and psychological processes that are difficult to study in rodents, particularly under anesthesia. Nevertheless, we do have some information as to how and when RVM nociceptive modulatory neurons are recruited to modulate nociceptive processing.

5.41.3.5.1 Response of RVM neurons to noxious stimulation: does pain inhibit pain?

Noxious-evoked withdrawals are associated with a period of on-cell activation and off-cell inhibition that can last from less than a second to many minutes. This period, during which the balance between the on- and off-cell populations is shifted toward on-cell activation, is associated with heightened nociceptive responsiveness that can be blocked by lesion of the RVM (Heinricher, M. M. *et al.* 1989; Ramirez, F. and Vanegas, H., 1989; Morgan, J. L. and Fields, H. L., 1994; Foo, H. and Mason, P., 2003). Thus noxious stimulation *per se* recruits the RVM to facilitate nociception. This conclusion is consistent with the early suggestion of Cervero F. and Wolstencroft J. H. (1984) that the RVM is part of a short-term positive feedback loop activated by noxious stimulation. Such a positive feedback process presumably prepares the organism to respond more briskly or at a lower threshold to subsequent damaging inputs. This view of on-cells as part of a positive feedback loop is further supported by evidence that on-cells are activated by acute cutaneous inflammation, and that the RVM is necessary for secondary hyperalgesia in this paradigm (Urban, M. O. *et al.*, 1996; Kincaid, W. *et al.*, in press).

The evidence for positive feedback mediated by the RVM is plainly at odds with the long-standing idea that pain inhibits pain, which arose from observations of an apparent lack of pain observed in some patients subjected to intense trauma (Wall, P. D. 1979; Melzack, R. *et al.*, 1982) and the from the ability of footshock or other noxious stimuli to suppress animals' responses to other painful events (Maier, S. F., 1986). Several factors must be considered in addressing this issue. First, other brainstem pathways, such as that through the medullary subnucleus reticularis dorsalis (Le Bars, D., 2002), act in parallel with the output from the RVM. The net effect of a given noxious stimulus on spinal nociceptive processing and pain sensation will reflect the actions of these pathways as well as that of the RVM. In addition, higher-order processes, such as fear or stress, are likely to be significant when an animal is subjected to an experimental noxious stimulus, particularly one over which it has no control. Such higher influences will be most prominent in awake behaving animals, and may shift the balance in the RVM towards activation of off-cells rather than on-cells. Such a shift is presumably the basis for stress-induced analgesia or antinociception associated with fear conditioning (Bodnar, R. J. *et al.*, 1980; Fanselow, M. S. 1986; Helmstetter, F. J. and Tershner, S. A., 1994). Conditioned fear, for example, produces antinociception mediated by the amygdala and the RVM, and direct opioid activation of the amygdala activates RVM off-cells via the PAG (Helmstetter, F. J. and Landeira-Fernandez, J., 1990; Helmstetter, F. J., 1992; Helmstetter, F. J. and Bellgowan, P. S., 1993; Helmstetter, F. J. and Tershner, S. A., 1994; Helmstetter, F. J. *et al.*, 1998; McGaraughty, S. and Heinricher, M. M., 2002; 2004).

Thus, because of higher-order inputs to the RVM and the actions of other descending pathways, the behavioral response to a given noxious stimulus may be enhanced or suppressed in the presence of pain. Which behavioral outcome predominates will depend on the stimulus history, the environment in which the stimulus is applied and the behavioral state of the animal.

5.41.3.5.2 Behavioral state control: anesthesia and sleep/waking cycle

The influence of behavioral state variables on nociceptive processing at the first central relay in the dorsal horn (Hayes, R. L. *et al.*, 1981; Bushnell, M. C. *et al.*, 1984; Soja, P. J. *et al.*, 1999) suggests that pathways descending from the brain to the dorsal horn contribute to the influence of behavioral state on nociception. One possibility that has been considered is that RVM neurons might mediate effects of general anesthesia or sleep/waking on nociceptive processing.

Correlative data suggest that on- and/or off-cell firing could contribute to isoflurane-induced motor depression at lighter planes of anesthesia (Jinks, S. L. *et al.*, 2004a). However, firing of both on- and off-cells is depressed when isoflurane concentration is increased to levels above that required to suppress nocifensor reflexes (Leung, C. G. and Mason, P., 1995). These neurons are thus unlikely to mediate the effects of a anesthesia at a surgical plane on nociceptive withdrawals.

Analysis of the role of on- and off-cells in mediating changes in nociception across the sleep–waking cycle is impeded by lack of a clear understanding of how nociception changes with sleep/waking. In cats, Kshatri A. M. *et al.* (1998) demonstrated that the latency of the tail flick reflex was slightly increased during slow-wave sleep compared to waking, but substantially longer during paradoxical sleep. Consistent with this, noxious-evoked activity of trigeminal neurons is depressed during paradoxical sleep, but not slow-wave sleep, compared to waking (Cairns, B. E. *et al.*, 1995; 1996). By contrast, Mason P. *et al.* (2001) reported that paw withdrawals evoked by heat were enhanced during slow-wave sleep compared to waking, suggesting a disinhibition of nociception during slow-wave sleep. Parallel recording studies from this group demonstrated that off-cells were more active during slow-wave sleep and on-cells and neutral cells were less active compared to waking (Leung, C. G. and Mason, P., 1999). It is therefore unlikely that on- or off-cells mediated the enhanced nociception seen in their behavioral analysis. However, these authors noted that rats return to sleep more quickly following noxious stimulation if the stimulus is delivered when the rats are sleeping rather than awake. They suggested that this could point to a role for off-cells in controlling arousal. However, it is not clear that the duration of waking triggered by the noxious stimulus could be differentiated from the ongoing waking pattern in their analysis. It remains to be determined whether off-cells control arousal, or mediate the influence of arousal on nociception.

A further question is whether on- and off-cells contribute to the atonia of paradoxical sleep. This has not been tested directly. However, although stimulation throughout the length of the medial pontomedullary reticular formation can produce atonia in decerebrate rats (Hajnik, T. *et al.*, 2000), the most effective sites are generally dorsal to the area defined as the RVM. Moreover, microinjection of kainate or morphine in the RVM in intact behaving rats does not produce loss of motor tone, even though locomotor activity in an open field is reduced (Morgan, M. M. and Whitney, P. K., 2000). Finally, the firing of on- and off-cells does not vary between slow wave sleep and paradoxical sleep (Foo, H. and Mason, P., 2003). Taken together, these data indicate that on- and off-cells are unlikely to mediate atonia during paradoxical sleep.

5.41.3.5.3 Micturition

Baez M. A. *et al.* (2005) recently reported that paw withdrawal to noxious heat is attenuated during micturition, presumably preventing potential interruption of bladder emptying by noxious stimulus-evoked movements. Consistent with the idea that off-cells inhibit and on-cells facilitate nociception during micturition, many presumptive off-cells were active during urine expulsion, whereas presumptive on-cells were inhibited. However, these authors propose a somewhat broader role for RVM neurons, as electrical stimulation in the RVM and morphine microinjection in the PAG are known to suppress bladder contractions (Sugaya, K. *et al.*, 1998; Matsumoto, S. *et al.*, 2004). Baez M. A. *et al.* (2005) therefore suggested that off-cell activation suppresses voiding, possibly by depressing transmission of bladder afferent information.

5.41.3.5.4 Environmental analgesia

Decreases in pain responsiveness can be induced by a wide range of experimental procedures, including electrical shock, forced swim, and centrifugal rotation (Watkins, L. R and Mayer, D. J., 1982; Bodnar, R. J., 1986; Maier, S. F., 1986). Biologically relevant threat stimuli such as odors from stressed animals of the same species or exposure to a predator also induce antinociception (Fanselow, M. S., 1985; Lester, L. S. and Fanselow, M. S., 1985; Kavaliers, M. 1988; Lichtman, A. H. and Fanselow, M. S., 1990). Activation of endogenous pain-modulating systems can also enhance the analgesic effects of exogenous opioids. Thus, presentation of a stressful shock potentiates morphine-induced antinociception, an effect that increases as the intensity of stress is increased (Grau, J. W. *et al.*, 1981; Rosellini, R. A. *et al.*, 1994). The PAG–RVM system is implicated in at least some of these environmentally induced changes in nociceptive responsiveness. Most important, some forms of environmental analgesia can be attenuated by lesioning the RVM (Prieto, G. J. *et al.*, 1983; Watkins, L. R. *et al.*, 1983b). Moreover, administration of a stressful foot shock blocks both the

pause in firing that characterizes off-cells and the typical on-cell burst of activity (Friederich, M. W. and Walker, J. M., 1990). This indicates that footshock and possibly other stressors affect the activity of on- and off-cell classes in a manner consistent with their respective pronociceptive and antinociceptive roles.

Antinociception is also elicited as a conditioned response to previously neutral cues paired with noxious or aversive events (Fanselow, M. S., 1986). This latter phenomenon is termed conditioned antinociception, and has been widely adopted for experimental analysis of endogenous mechanisms involved in nociceptive modulation. In conditioned antinociception paradigms, antinociception is recruited in concert with other behaviors and autonomic adjustments as part of a defensive reaction (Williams, F. G. *et al.*, 1990; Fanselow, M. S., 1991; Harris, J. A. and Westbrook, R. F., 1995). Benzodiazepine receptor inverse agonists have anxiogenic or fear-promoting effects, and yield antinociception after either intracerebral or systemic administration (Rodgers, R. J. and Randall, J. I., 1988; Helmstetter, H. J. *et al.*, 1990; Fanselow, M. S. and Kim, J. J., 1992). Conversely, hypoalgesia is reduced by manipulations that would be expected to reduce fear, such as administration of anxiolytic agents (Fanselow, M. S. and Helmstetter, H. J., 1988).

The amygdala, a forebrain structure with a well-documented role in fear, stress and anxiety, is critical in organization of the fear-related processes described above (Davis, M., 1992a; 1992b). Notably, amygdala lesions attenuate freezing and analgesia in rats exposed to a cat, which is an innate fear stimulus for this species (Blanchard, D. C. and Blanchard, R. J., 1972; Fox, R. J. and Sorenson, C. A., 1994), and to intense, nonnoxious noise (Helmstetter, F. J. and Bellgowan, P. S., 1994; Bellgowan, P. S. and Helmstetter, F. J., 1996). Such lesions have no effect on baseline nociceptive responsiveness (Helmstetter, F. J. 1992; Fox, R. J. and Sorenson, C. A., 1994; Manning, B. H. and Mayer, D. J., 1995; Watkins, L. R. *et al.*, 1993).

Antinociception produced by fear-related processes organized in the amygdala is mediated by the PAG–RVM system. Thus, conditioned antinociception involves suppression of nociceptive processing at the level of the spinal cord (Harris, J. A. *et al.*, 1995), and is disrupted by lesions of the PAG or the RVM, or by infusion of an opiate antagonist into the PAG (Watkins, L. R. *et al.*, 1983a; 1983b; Kinscheck, I. B. *et al.*, 1984; Helmstetter, F. J. and Landeira-Fernandez, J., 1990; Helmstetter, F. J. and Tershner, S. A., 1994). The amygdala sends a sparse projection into the RVM region, raising the possibility that the amygdala could directly influence the RVM (Price, J. L. and Amaral, D. G., 1981; Hermann, D. M. *et al.*, 1997). However, the projection from the amygdala to the PAG is much more robust, and the PAG is thought to be a necessary relay in the antinociception associated with conditioned fear. Amygdala projections to the PAG arise from the central nucleus, and to a lesser extent the medial nucleus (Krettek, J. E. and Price, J. L., 1978; Rizvi, T. A. *et al.*, 1991; Canteras, N. S. *et al.*, 1995). Terminations from the central nucleus are concentrated in PAG regions that in turn send projections to the RVM (Rizvi, T. A. *et al.*, 1991). Activation of the central or basolateral nucleus of the amygdala alters the firing of PAG neurons, with approximately equal proportions of PAG neurons showing excitation and inhibition (Sandrew, B. B. and Poletti, C. E., 1984; da Costa Gomez, T. M.and Behbehani, M. M., 1995). Effects of basolateral stimulation are mediated primarily through the central nucleus (da Costa Gomez, T. M. *et al.*, 1996). Finally, microinjection of morphine in the basolateral nucleus of the amygdala activates off-cells and suppresses on-cell firing, and these changes in on- and off-cell activity are associated with behavioral antinociception (McGaraughty, S. and Heinricher, M. M., 2002). Taken together, the above findings indicate that one way in which the modulatory circuitry of the PAG–RVM circuitry is engaged physiologically is via activation of the amygdala by stimuli that induce fear.

5.41.4 Conclusion

The effort to understand the neural basis of nociceptive modulation by the PAG–RVM system highlights the importance of studying functionally identified neurons. The RVM can both facilitate and inhibit nociception. Furthermore, this region is also implicated in a number of functions other than nociceptive modulation, including reproductive behaviors, cardiovascular and respiratory control, sleep–waking and arousal, thermoregulation, and behavioral suppression. A meaningful analysis of how the RVM contributes to enhanced pain states therefore requires functional identification of the neurons under study, so that mechanisms contributing to nociceptive facilitation can be distinguished from those involved in nociceptive inhibition or other functions. The

on/off/neutral cell classification introduced over 20 years ago by Fields H. L. *et al.* (1983a) has been very productive. It has predicted the pharmacology of individual neurons (responses to opioids, norepinephrine, cannabinoids, neurotensin, and CCK) and allowed functional links between activation of on-cells and increased nociception, and between activation of off-cells and decreased nociception. Application of a similar analysis to the PAG, which is implicated in a host of functions from autonomic control to reproductive behavior and vocalization, would greatly advance our understanding of the neural circuitry of pain modulation in this region.

Numerous neurotransmitters and neuropeptides have been implicated in pain modulating functions of the PAG and RVM. Under what conditions are these substances released? Are they local or external to the PAG–RVM? Anatomical studies document substantial reciprocal connections between the PAG and limbic forebrain structures. Which of these connections are relevant to pain modulation, and under what conditions are they activated? These and similar questions must be addressed in order to meet the greater challenge of defining how and when this system is brought into play to enhance or inhibit pain.

5.42.1 More than a Sensation?

In a provocative article entitled *On the Relation of Injury to Pain*, Wall P. D. (1979) suggested that "... pain is better classified as an awareness of a need state than as a sensation; that it has more in common with the phenomena of hunger and thirst than it has with seeing and hearing ...." He also observed, somewhat anecdotally, that as pain changed from acute to chronic the emotional coping reaction also changed. Livingston W. K. (1998) in his posthumously published book *Pain and Suffering* stated a similar belief that "... pain is not strictly a physical sensation that can be defined simply by its anatomical and physiological substrates." Writing even earlier, Lewis T. (1942) observed that different emotional coping reactions were evoked by pain of different tissue origins, "... while painful sensations derived from the human skin are associated with brisk movements, with a rise of pulse rate and with a sense of invigoration ... painful sensations derived from deeper structures are associated often with quiescence, with slowing of the pulse, falling of the blood pressure, sweating and nausea." He went on to suggest that "... the difference in the quality of skin pain and of deep pain is so clear ... that it would perhaps seem unsafe to class both together under the one unqualified term pain and concluded that "... we should bear in mind the possibly serious fallacy of regarding both types (of pain) as represented in a common centre."

It is striking that these eminent researchers although starting from different perspectives arrive at a shared view, namely, that in addition to knowledge of the anatomy and physiology of its ascending sensory pathways, understanding how pain is localized in the brain also requires knowledge of the neurobiology of the emotional coping strategies triggered by different classes of pain.

5.42.2 Coping with Pain

5.42.2.1 Active versus Passive Emotional Coping

Animals (including humans) employ different strategies to cope with different classes of pain. Active emotional coping, which is characterized by engagement with the environment (i.e., fight or flight), is the usual response to escapable pain. Components of active coping include increased vigilance, hyperreactivity, increased somatomotor activity, and increased sympathetic activity. Passive emotional coping, is the antithesis of active coping. Instead of engagement with the environment, there is disengagement (e.g., conservation-withdrawal (Henry, J. P. and Stephens, P. M., 1977)). Components of passive coping include: decreased vigilance, hyporeactivity, quiescence, and falls in arterial pressure and heart rate. Passive

emotional coping is the usual response to inescapable pain, i.e., pain of deep origin (muscle, joint, viscera) or any persistent/chronic pain (Lewis, T., 1942; Wall, P. D., 1979; Bandler, R. *et al*., 2000; Keay, K. A. *et al*., 2001).

5.42.2.2 Neural Representations of Active Emotional Coping

Research carried out in rats, cats, and primates has identified longitudinally oriented, neuronal columns within the midbrain periaqueductal gray (PAG) as critical substrates integrating active or passive emotional coping. As seen in Figure 1 active emotional coping responses (i.e., a coordinated reaction of freezing, fight or flight, hypertension, tachycardia, and a nonopioid-mediated analgesia) are evoked when excitatory amino acids are microinjected into either the dorsolateral (dlPAG) or lateral (lPAG) column. (Bandler, R. and Shipley, M. T., 1994). Anatomical and functional studies suggest, however, different neural circuits and triggers are involved.

5.42.2.2.1 Dorsolateral periaqueductal gray

The dlPAG is distinguished from the lPAG by the presence (e.g., nitric oxide synthase (NOS), cholecystokinin (CCK), acetylcholine (ACh), Met-enkephalin) or absence (e.g., cytochrome oxidase and Gly-2 transporter) of specific neurochemicals (for a review, see Keay, K. A. and Bandler, R., 2004). Anatomically, major descending inputs to dlPAG originate from medial prefrontal cortical (PFC) fields and select medial hypothalamic nuclei, but there is a striking absence of ascending afferents arising from either brainstem or spinal cord (Figure 2). The predominance of forebrain, primarily cortical inputs, led to the suggestion that when triggered by psychological (cortical) stimuli, active coping is mediated by the dlPAG (Bandler, R. *et al*., 2000). Consistent with this suggestion, the potential threat signaled by the presence of a cat (sight and/or odor, but without physical contact) triggers active coping and a selective increase in immediate early gene (c-fos) expression in the dlPAG of the rat (Figure 2) (Canteras, N. S. and Goto, M., 1999).

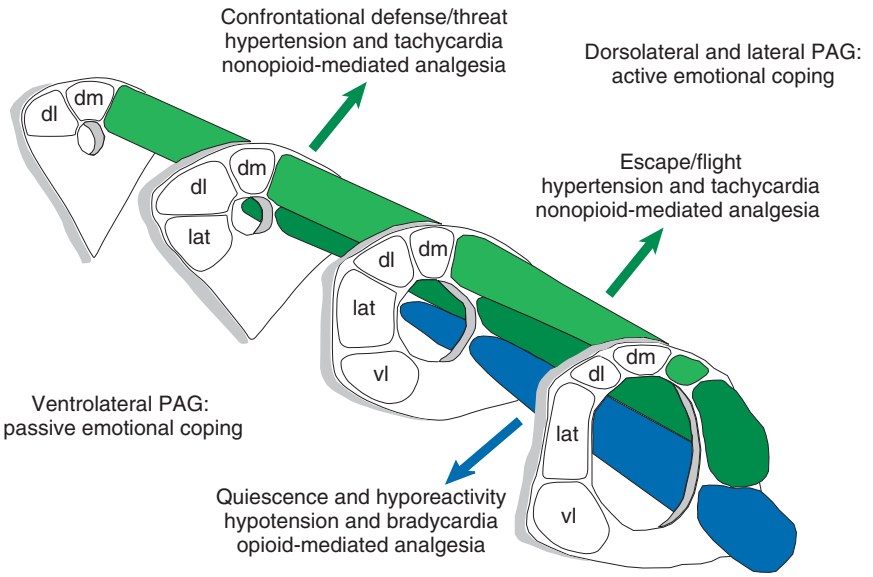

Figure 1 Schematic illustration of the dorsomedial (dm), dorsolateral (dl), lateral (lat), and ventrolateral (vl) neuronal columns within the periaqueductal gray (PAG). Injections of excitatory amino acids (EAA) within the dorsolateral and lateral PAG evoke active emotional coping strategies, whereas passive emotional coping strategies are evoked from the ventrolateral PAG. Specifically, EAA injections made within the dlPAG and lPAG columns evoke defensive reactions (confrontation, threat, escape, flight), hypertension, tachycardia, and a non-opioid-mediated analgesia. In contrast, EAA injections made within the vlPAG evoke cessation of spontaneous activity (quiescence), decreased responsiveness to the environment (hyporeactivity), hypotension, bradycardia, and an opioid-mediated analgesia. Adapted from Bandler, R. and Shipley, M. T. 1994. Columnar organization in the midbrain periaqueductal gray: modules for emotional expression? Trends Neurosci. 17, 379–389.

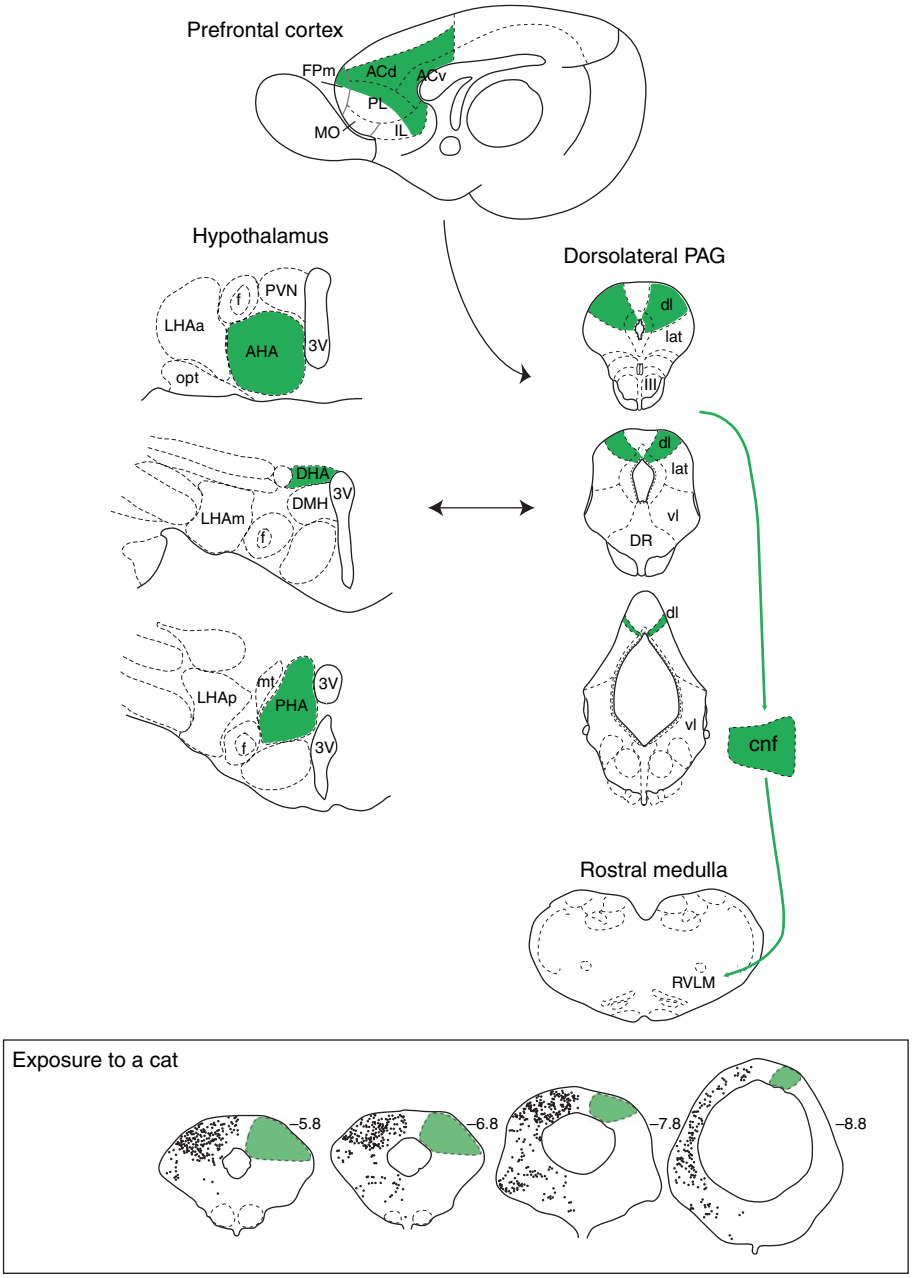

Figure 2 Schematic illustration of the major afferent and efferent projections of the dorsolateral periaqueductal gray (dlPAG). Major forebrain inputs to the dlPAG arise from dorsal, medial prefrontal cortical fields, and medial hypothalamic regions. The dlPAG does not project directly to the medulla, but can influence the rostral ventrolateral medulla via the cuneiform nucleus (cnf). The lower panel illustrates the pattern of neural activation (c-fos expression) evoked by a psychological stressor (exposure, without physical contact, of a rat to a cat), which evokes active emotional coping. The shaded area indicates the dorsolateral PAG column. RVLM, rostral ventrolateral medulla ACd, dorsal anterior cingulate cortex; ACv, ventral anterior cingulate cortex; AId, dorsal agranular insular cortex; AIp, posterior agranular insular cortex; DLO, dorsolateral orbital cortex; FPm, medial frontal pole; IL, infralimbic cortex; MO, medial orbital cortex; PL, prelimbic cortex; PRh, perirhinal cortex; VLOm, ventrolateral orbital cortex, medial part; VO, ventral orbital cortex AHA, anterior hypothalamic area; DHA, dorsal hypothalamic area; DMH, dorsomedial hypothalamic area; LHAa, lateral hypothalamic area, anterior; LHAm, lateral hypothalamic area, medial; LHAp, lateral hypothalamic area, posterior; PHA, posterior hypothalamic area; PVN, periventricular hypothalamic nucleus; f, fornix; mt, mamillothalmic tract; opt, optic tract; 3V, third ventricle; dl, dorsolateral PAG; lat, lateral PAG; vl, ventrolateral PAG, DR, dorsal raphe. Exposure to a cat: Adapted from Canteras, N. S. and Goto, M. 1999. Fos-like immunoreactivity in the periaqueductal gray of rats exposed to a natural predator. Neuroreport 10, 413–418.

5.42.2.2.2 Lateral periaqueductal gray

Although the boundary between the lPAG and dlPAG can be established on neurochemical grounds, the boundary between the lPAG and ventrolateral periaqueductal gray (vlPAG) rests on functional criteria (see Figure 1 and Section 5.42.2.3). Anatomically, the lPAG receives modest descending afferents of cortical and dorsal hypothalamic origins. However, in contrast to the dlPAG, the lPAG receives substantial and somatotopically organized ascending inputs from laminae I, II, IV, and V of the spinal cord, as well as the caudal, spinal trigeminal complex (Sp5) (Figure 3). The predominance of inputs arising from noci-responsive spinal and SpV regions suggests that active coping in response to physical stimuli (e.g., acute cutaneous pain) is mediated by the lPAG. In support of this hypothesis, brief applications of a noxious, cutaneous (thermal) stimulus evoked increased *Fos* expression within the lPAG, hypertension and active coping (Figure 3) (Keay, K. A. and Bandler, R. 1993; 2002).

5.42.2.3 Neural Representation of Passive Emotional Coping

Passive coping (i.e., a coordinated, conservation-withdrawal reaction of quiescence, hyporeactivity, hypotension, bradycardia, and an opioid-mediated analgesia) is evoked by microinjection of excitatory amino acids into the vlPAG column (Figure 1) (Bandler, R. and Shipley, M. T., 1994; Keay, K. A. and Bandler, R., 2001).

5.42.2.3.1 Ventrolateral periaqueductal gray

In common with the lPAG, substantial ascending inputs to the vlPAG originate from superficial and deep dorsal horn of spinal cord (and the transition zone between caudal and interpolar parts of Sp5, personal observations) (Keay, K. A. *et al.*, 1997). Double-label anatomical tracing studies indicate, however, that vlPAG and lPAG projections arise from distinct and separate populations of spinal neurons (Clement, C. I. *et al.*, 2000). Further, spino-vlPAG projections are not somatotopically organized (Keay, K. A. *et al.*, 1997). The vlPAG also receives substantial ascending inputs from nuclei of the solitary tract (NTS), as well as descending inputs from select orbital and insular cortical fields and the lateral hypothalamus (Figure 4). The convergence within the vlPAG of spinal, medullary, and forebrain afferents suggests that passive coping, whether evoked by physical or psychological stimuli, is mediated by the vlPAG. In support of this view, Fos expression is strongly evoked in the vlPAG when passive coping is triggered either (1) as a primary response to a deep or persistent noxious stimulus (see Figure 4) (Clement, C. I. *et al.*, 1996; Keay, K. A. *et al.*, 1997; 2001; Keay, K. A. and Bandler, R., 2002) or (2) in order to promote recovery and healing, as a delayed response to acute injury (for a discussion, see Wall, P. D., 1979; Keay, K. A. and Bandler, R., 2004).

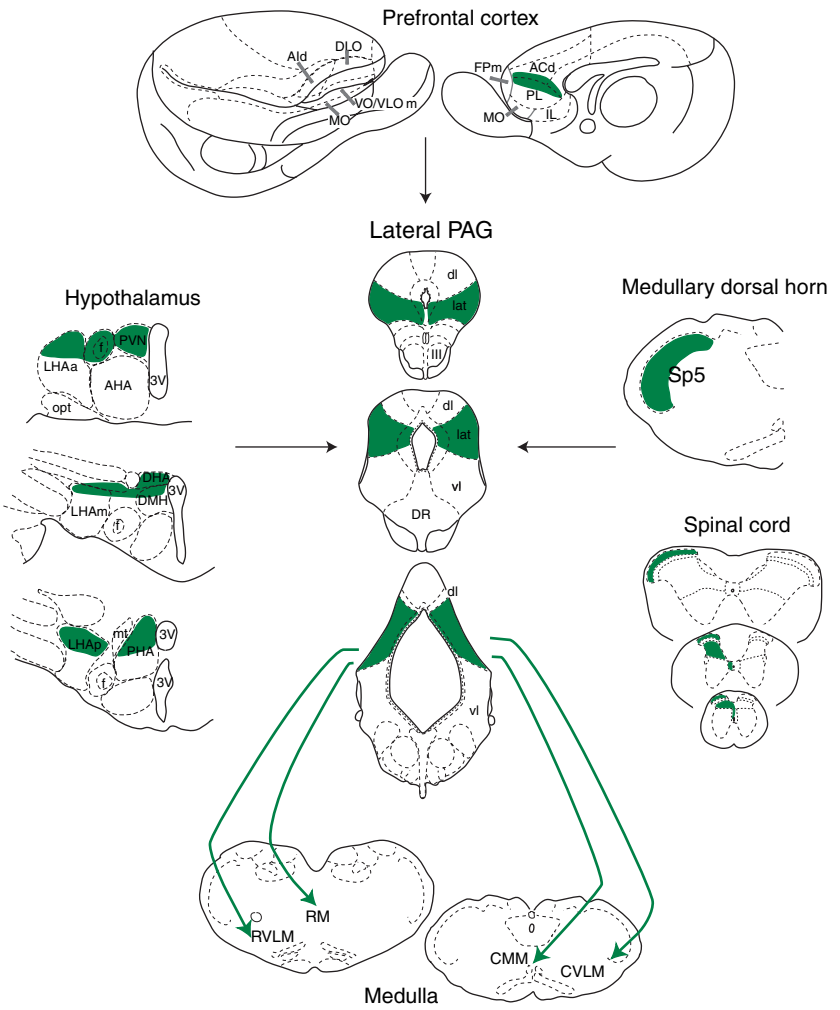
5.42.2.4 Outputs Mediating Active and Passive Emotional Coping

5.42.2.4.1 Lateral periaqueductal gray and ventrolateral periaqueductal gray

Although they mediate distinct emotional coping strategies, the same ventromedial and ventrolateral medullary regions are projected upon by lPAG and vlPAG (see Figures 3 and 4) (Keay, K. A. and Bandler, R., 2001). Consistent with the opposing functional roles of lPAG and vlPAG, electrophysiological studies reveal opposite effects on medullary target neurons. For example, presympathetic rostral ventrolateral medulla (RVLM) vasopressor neurons are excited by lPAG stimulation, but inhibited by vlPAG stimulation (Verberne, A. J. and Boudier, H. R. S., 1991; Lovick, T. A., 1992a; 1992b; Verberne, A. and Guyenet, P., 1992). In contrast to shared descending targets, there exist distinct ascending projections to specific hypothalamic and midline and intralaminar thalamic fields (Floyd, N. S. *et al.*, 1996; 2000; Krout, K. E. and Loewy, A. D., 2000; Floyd, N. S. *et al.*, 2001).

5.42.2.4.2 Dorsolateral periaqueductal gray

Although it integrates an identical emotional coping strategy to the lPAG, the dlPAG has few direct medullary outputs. Its influence on the ventrolateral medulla is likely mediated indirectly, in part via a substantial projection to the cuneiform region (see Figure 2) (Redgrave, P. *et al.*, 1988; Mitchell, I. J. *et al.*, 1988a; 1988b). The dlPAG also projects to distinct thalamic and hypothalamic fields (Floyd, N. S. *et al.*, 1996; 2000; Krout, K. E. and Loewy, A. D., 2000; Floyd, N. S. *et al.*, 2001).



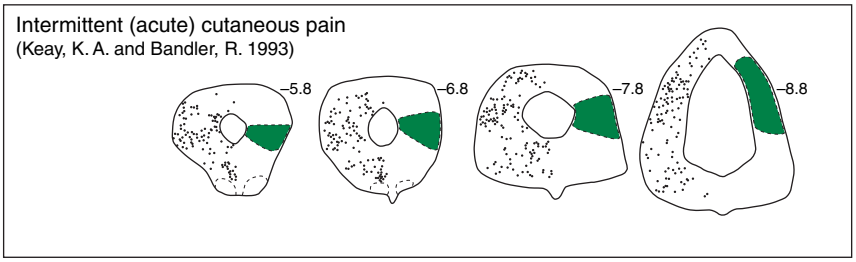


Figure 3 Schematic illustration of the major afferent and efferent projections of the lateral periaqueductal gray (lPAG). Major inputs to lPAG arise from spinal cord and the medullary dorsal horn (spinal trigeminal complex (SpV)). In addition, more modest inputs arise from a restricted part of medial prefrontal cortex as well as dorsal hypothalamic regions. The lPAG projects directly to both the rostral and caudal ventrolateral medulla (RVLM, CVLM), as well as the rostral and caudal ventromedial medulla (RM, CMM). The panel in the lower part of the figure shows the pattern of neural activation (c-fos expression) evoked by an acute cutaneous noxious stimulus (intermittent radiant heat), which evokes active emotional coping. The shaded area indicates the lPAG column. For abbreviations see caption to Figure 2.

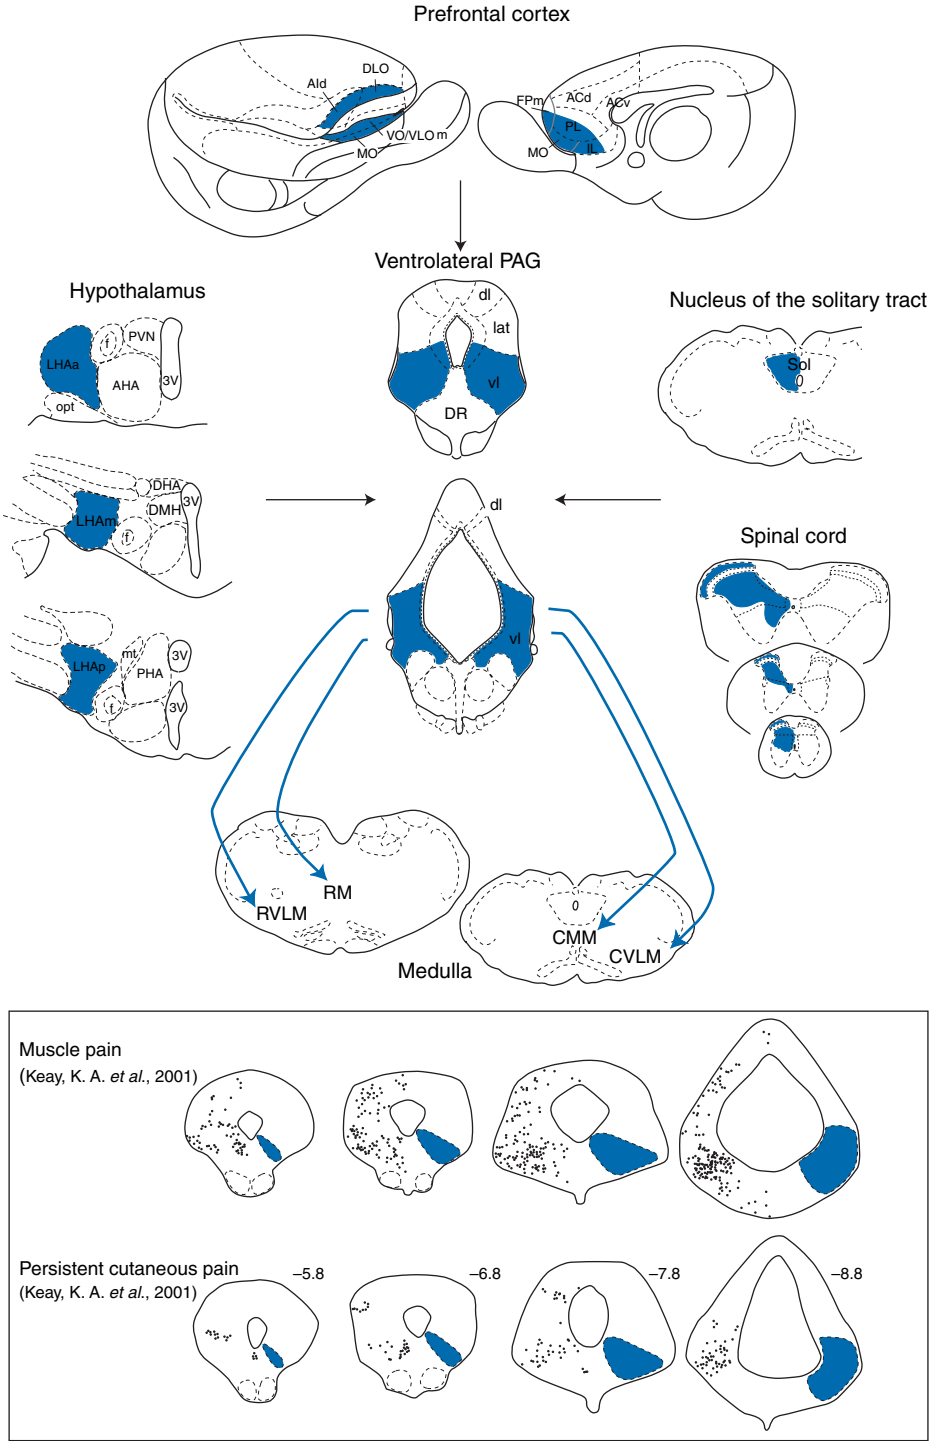

Figure 4 Schematic illustration of the major afferent and efferent projections of the ventrolateral periaqueductal gray (vlPAG). Major inputs to vlPAG arise from spinal cord and the nucleus of the solitary tract. In addition, significant inputs arise also from ventromedial prefrontal cortex and orbital/insular cortices. As well, substantial inputs arise from lateral hypothalamic fields. The vlPAG projects directly to both rostral and caudal ventrolateral medulla (RVLM, CVLM), as well as the rostral and caudal ventromedial medulla (RM, CMM). The panel in the lower part of the figure shows the patterns of neural activation (c-fos expression) evoked by an acute deep noxious stimulus (muscle pain: i.m. formalin) and a persistent cutaneous noxious stimulus (clip applied to dorsum of neck), each of which evoke passive emotional coping. The shaded area indicates the vlPAG column. For abbreviations see caption to Figure 2.

5.42.3 Conclusion

Animals (including humans) share the capacity to respond to escapable or inescapable pain with different emotional coping strategies. It has been established that the PAG is divisible into distinct longitudinal neuronal columns, which mediate distinct coping strategies (dlPAG/lPAG: active emotional coping; vlPAG: passive emotional coping). Further, each PAG column lies embedded within parallel, but distinct circuits, which extend rostrally to include specific PFC and hypothalamic regions (Bernard, J. F. and Bandler, J. F., 1998; Keay, K. A. and Bandler, R., 2001). On the output side, each PAG column projects either directly (lPAG/vlPAG) or indirectly (dlPAG) onto ventrolateral and ventromedial medullary regions containing (1) somatic and autonomic premotor neurons and (2) neurons mediating antinociception. A substantial body of evidence supports the view that the different PAG columns, and, their associated circuits, play critical roles in integrating the somatic, autonomic and antinociceptive components which characterize the distinct emotional coping reactions evoked by pain of different tissue origins and/or durations.

5.43.1 Introduction

The thalamus has been recognized to play a very important role in the higher-level processing of nociceptive inputs ever since the clinical observations by Dejerine J. and Roussy G. (1906) and Head H. and Holmes G. (1911) of pain resulting from strokes affecting the lateral thalamus. Modern-day anatomical and electrophysiological techniques have provided a wealth of information regarding the processing of nociceptive information at the thalamic level.

The concept that medial thalamus is involved in the affective/motivational aspect of pain and the lateral thalamus in the sensory/discriminative aspect of pain originated with the comprehensive analysis of 23 thalamic pain patients by Head and Holmes, and it was emphasized particularly by Melzack R. and Casey K. L. (1968). For many years, the available anatomical and physiological evidence suggested that these functions be ascribed to indirect spinoreticulothalamic (paleospinothalamic) input to medial thalamus and direct (neospinothalamic) spinothalamic tract (STT)-mediated input to somatosensory lateral thalamus, which was most prominent in humans. However, the recent evidence summarized below indicates that lamina I STT input to distinct portions of medial and lateral thalamus can be directly associated with these functions.

This chapter will review the major findings relating to the anatomy, physiology, and pharmacology of thalamus with respect to understanding its role in the mediation of acute and chronic pain. The chapter will start with an overview of thalamic anatomy and the termination sites of ascending somatosensory pathways focusing on the STT in the primate. Then the physiological findings in animals will be summarized, followed by discussions of findings in humans and a summary of thalamic pharmacology.

5.43.2 Comparative Anatomical Findings

In contrast to spinal cord, there are significant species differences in the anatomy of the pathways and the nuclei mediating nociception at the thalamic level. This chapter will focus on findings from primates including humans and will commence with a description of the thalamic termination sites of ascending pathways involved in the transmission of nociceptive information. The major pathway involved in the relay of nociceptive and thermoreceptive information is the STT and the functionally equivalent component of the trigeminothalamic tract (TTT) that originates in the medullary dorsal horn (subnucleus caudalis of the trigeminal spinal tract nucleus, also termed the medullary dorsal horn). Although the STT is frequently described as a single tract, this chapter will describe separately the terminations of its two components, the lateral and the ventral. The lateral STT originates largely from lamina I of the superficial dorsal horn and contains many neurons responding specifically to noxious stimuli and innocuous thermoreceptive neurons. In contrast, the ventral STT originates largely from neurons in deeper layers, most of which respond to innocuous tactile and proprioceptive inputs in addition to nociceptive inputs (Craig, A. D. and Dostrovsky, J. O., 1999; Craig, A. D., 2003).

5.43.2.1 Thalamic Nuclei Receiving Direct Spinothalamic Tract Inputs

There are six major regions of termination of the STT and TTT within the primate thalamus: the ventroposterior nucleus (VP), the posterior portion of the ventromedial nucleus (VMpo), the ventrolateral nucleus (VL), the central lateral nucleus (CL), the parafascicular nucleus (Pf), and the ventrocaudal portion of the medial dorsal nucleus (MDvc) (Mehler, W. R., 1969; Boivie, J., 1979; Berkley, K. J., 1980; Craig, A. D., 2003; 2004). Each of these is described in more detail below.

5.43.2.1.1 Ventroposterior nuclei

The VP that comprises the ventroposterior lateral (VPL) and ventroposterior medial (VPM) nuclei receives its major ascending afferent input from the medial lemniscus and is the main relay nucleus for tactile and kinesthetic information. This nucleus is also frequently termed the ventrobasal complex and in the human, the ventrocaudal nucleus (Vc) (Hassler, R., 1959; Mehler, W. R., 1966; Jones, E. G., 1990). However, it is well established that the STT and TTT also have terminations in this region. The STT terminations in VP form clusters (also referred to as archipelago), which are especially dense along its caudal border with the posterior group and pulvinar and along its rostral border with the VL and near the laminae that occur within VP (Stepniewska, I. *et al.*, 2003). The terminations are roughly in register with the detailed somatotopic organization of the low-threshold mechanoreceptive (LTM) lemniscal terminations and thalamocortical neurons, with craniofacial inputs to VPM, arm/forelimb inputs to medial VPL, and leg/hindlimb inputs to lateral VPL. Some of the STT axons terminating in VP also send a collateral into the CL (Applebaum, A. E. *et al.*, 1979; Giesler, G. J. Jr. *et al.*, 1981).

The main source of STT and TTT terminations in VP is from the neurons in the deep dorsal horn (laminae IV and V) as shown in Figure 1(b). Interestingly, these terminations appear directed to VP neurons that are immunopositive for calbindin in contrast to the lemniscal afferents from the dorsal column nuclei (DCN) and principal trigeminal nucleus, which terminate in the vicinity of neurons that are immunopositive for parvalbumin (Rausell, E. and Jones, E. G., 1991). Furthermore, the calbindin-immunopositive neurons project to the superficial layers of cortex, whereas the parvalbumin neurons project to the middle layers (Gingold, S. I. *et al.*, 1991; Rausell, E. and Jones, E. G., 1991). Another difference between spinothalamic and lemniscal terminations is that the latter but not the former form triadic synapses with GABAergic presynaptic dendrites (Ralston, H. J., III and Ralston, D. D., 1994). These differences suggest that the spinothalamic nociceptive inputs are processed differently than the innocuous mechanoreceptive inputs in VP.

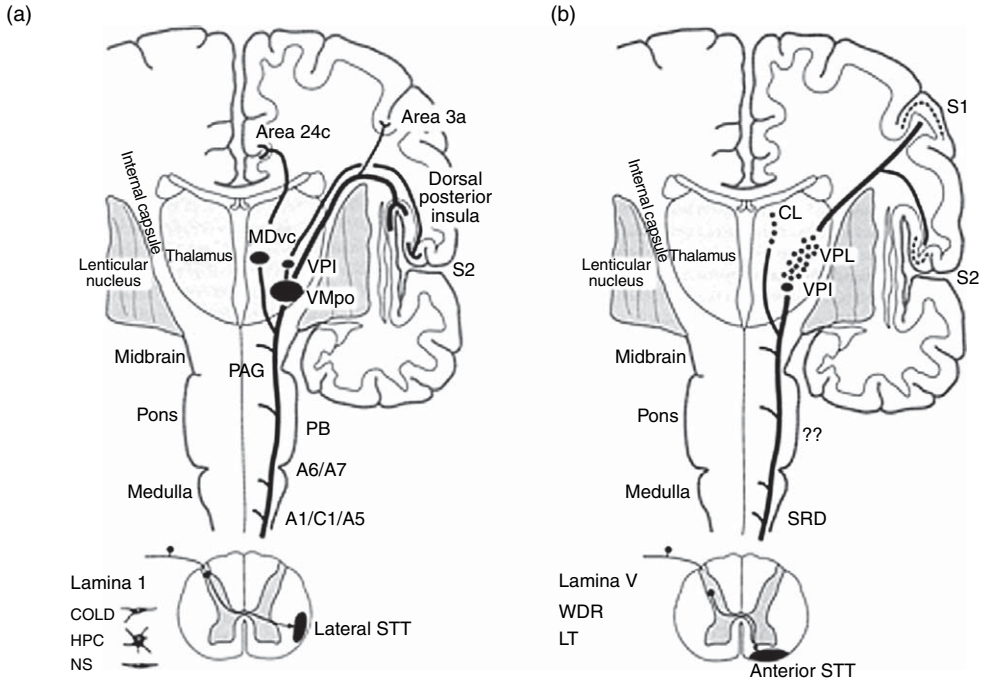

Figure 1 A schematic summary diagram of the ascending projections from the spinal cord to the thalamus and on to the cortex. (a) The lateral spinothalamic tract arising from nociceptive (HPC and NS) and innocuous thermoreceptive (COLD) neurons in lamina I. The major thalamic termination sites are in the posterior part of the ventromedial nucleus (VMpo), ventroposterior inferior nucleus (VPI), and the ventrocaudal part of the medial dorsal nucleus (MDvc). Also shown are the brainstem terminations in the ventrolateral medulla (A1/C1/A5), the dorsolateral pons (A6/A7), the parabrachial nucleus (PB), the periaqueductal gray (PAG), and the cortical projections of the thalamic sites receiving the lamina I inputs. (b) The ascending projections of lamina IV–V cells, primarily wide dynamic range (WDR) neurons and low-threshold mechanoreceptive (LTM) neurons, via the ventral spinothalamic tract (STT) to the VPI, ventroposterior lateral nucleus (VPL), ventrolateral nucleus (VL), and central lateral nucleus (CL). Terminations also occur in the brainstem in the subnucleus reticularis dorsalis (SRD) and other sites, probably including the reticular core. Adapted with permission from Craig, A. D. and Dostrovsky, J.O. 1999. Medulla to Thalamus. In: Textbook of Pain (*eds*. P. D. Wall and R. Melzack), pp. 183–214. Churchill-Livingstone.

Immediately ventral to VPL and VPM lies the ventroposterior inferior nucleus (VPI; roughly equivalent to the parvicellular part of the ventrocaudal nucleus (Vcpc) in humans). Curiously, this nucleus receives STT and TTT inputs from neurons located not only in laminae IV and V but also in lamina I, as well as from vestibular afferents (Ralston, H. J., III and Ralston, D. D., 1992). The VPI projects to secondary somatosensory cortex (SII) and retroinsular (vestibular) cortex (Friedman, D. P. and Murray, E. A., 1986; Stevens, R. T. *et al*., 1993).

Species differences. In the rat, there are STT and TTT terminations throughout VP (Mehler, W. R., 1969; Peschanski, M., 1984), which originate from both superficial and deep layers of the dorsal horn. In contrast, in the cat, the STT and TTT terminate along the ventral aspect of VPL (and VPI and the basal part of the ventromedial nucleus (VMb)) and there are almost no terminals within VP (Berkley, K. J., 1980; Craig, A. D. and Burton, H., 1985).

5.43.2.1.2 Posterior part of the ventromedial nucleus

Recent studies in the monkey have revealed that there is a very prominent and dense projection from STT and TTT neurons in lamina I to a region that has been termed the posterior ventromedial nucleus (VMpo), which lies immediately posterior and inferior to VP and is contiguous rostrally with the VMb (Craig, A. D., 2004). Of particular interest and importance are the findings that the STT and TTT terminations are topographically organized (Craig, A. D., 2003; 2004) and that the VMpo neurons project in a topographic manner to the dorsal posterior insula, a region that is consistently activated by thermal and nociceptive stimuli. The VMpo is the

major projection target of the lamina I neurons in the primate, which comprise its almost exclusive ascending sensory input (Figure 1(a)). The trigeminal inputs terminate anteriorly and lumbar inputs most posteriorly. This anteroposterior topographic arrangement contrasts with the mediolateral topography of the VP.

The dense lamina I STT and TTT terminations in VMpo are clearly delineated with the use of immunohistochemical labeling for calbindin. A region of calbindin-positive terminal labeling has been observed in a comparable location in the human thalamus (Blomqvist, A. *et al.*, 2000) and corresponds with the area of dense STT terminations observed in thalamus following cordotomies performed to alleviate pain (Mehler, W. R., 1966). This region can also be delineated in monkeys and humans based on its different cytoarchitecture. Electron microscopy has revealed that the glutamatergic STT and TTT terminations form triadic synapses with the VMpo relay cell dendrites and GABAergic presynaptic dendrites (Beggs, J. *et al.*, 2003). This is similar to the termination of lemniscal afferents in VP but contrasts with the STT terminations in VP. The triadic contacts are believed to provide high synaptic security and temporal fidelity. VMpo was not specifically identified in earlier anatomical studies, but the region was included in the caudal VP (Mehler, W. R., 1966), the Vc portae (Hassler, R., 1970), and the posterior complex (Po) (Jones, E. G., 1990).

Species differences. In the cat, there is a sparse lamina I terminal field in the ventral VMb, and this may constitute a primordial homologue of the primate VMpo. In support of this notion is the fact that lesions to this part of VMb in the cat disrupt discriminative thermal sensation (Norrsell, U. and Craig, A. D., 1999) and that it projects to insular cortex (Clasca, F. *et al.*, 1997). A homologous region does not appear to exist in the rat.

5.43.2.1.3 Ventral lateral nucleus

Moderately dense STT terminations are observed extending rostrally from VP into caudal VL in cats and monkeys that overlap with inputs from the cerebellum (Berkley, K. J., 1980; Stepniewska, I. *et al.*, 2003). These inputs probably originate from neurons in the deep dorsal horn and ventral horn (laminae V and VII). VL projects to the motor cortex (Jones, E. G., 1985), and this STT component is most likely related with sensorimotor integration rather than nociception.

5.43.2.1.4 Parafascicular nucleus

The centré median (CM) and Pf regions are frequently cited as playing a major role in nociception. However, there is only a weak STT projection to Pf that originates from lamina I and V cells, and more recent anatomical studies fail to confirm earlier reports of STT terminations in CM. The Pf and CM nuclei appear to be involved in motor-related processing as their main connections are with the basal ganglia, substantia nigra, and motor cortex (Jones, E. G., 1985; Royce, G. J. *et al.*, 1989; Sadikot, A. F. *et al.*, 1992).

5.43.2.1.5 Medial dorsal nucleus

Recent studies in the monkey reveal moderately dense STT and TTT projections to the MDvc. The terminals are topographically organized along an anteroposterior axis, with trigeminal input located most posteriorly. The cells of origin of this projection are in lamina I of the spinal and medullary dorsal horn (Ganchrow, D., 1978; Craig, A. D., 2004). Cells in MDvc project to area 24c in the cortex at the fundus of the anterior cingulate sulcus (limbic motor cortex), rather than to the orbitofrontal and prefrontal cortex where the remainder of medial dorsal nucleus (MD) projects (Ray, J. P. and Price, J. L., 1993; Craig, A. D., 2003). It is likely that this region of MD plays an important role in mediating the affective/motivational aspect of pain. There appears to be no homologous region in the cat or rat (see Section 5.43.2.1.7).

5.43.2.1.6 Central lateral nucleus

Dense STT terminations are observed in the caudal part of CL and in some other portions of the nucleus. The cells of origin are located in laminae V and VII (Applebaum, A. E. *et al.*, 1979; Giesler, G. J., Jr. *et al.*, 1981; Craig, A. D., Jr. *et al.*, 1989). Projections from different regions of the spinal cord terminate in different cell clusters but do not appear to be topographically organized (Craig, A. D. and Burton, H., 1985). This nucleus also receives projections from the cerebellum, tectum, substantia nigra, and globus pallidus. Most of the neurons in this region project to the basal ganglia, but there are also projections to the superficial and deep layers of posterior parietal and motor cortices (Jones, E. G., 1985; Royce, G. J. *et al.*, 1989). The function of the STT input to this nucleus is unknown, but one can speculate that it may be involved in motor set, attention, and orientation. Similar STT terminations have been observed in cats, rats, and other vertebrates.

5.43.2.1.7 *Nucleus submedius*

In the cat, there are dense and topographically organized terminations of the TTT and STT arising from spinal and medullary dorsal horn lamina I neurons in the medial thalamic nucleus submedius (Sm). Although Sm originates developmentally from the pronucleus of MD, it projects to the ventrolateral orbital cortex rather than to the cingulate cortex and thus constitutes a major phylogenetic difference from the lamina I projection to MDvc in the primate (Craig, A. D., Jr. *et al.*, 1982; Coffield, J. A. *et al.*, 1992). In the cat, the spinal input to the anterior cingulate relays in the ventral VP (Musil, S. Y. and Olson, C. R., 1988; Yasui, Y. *et al.*, 1988) and also indirectly by way of the parabrachial nucleus (PB) (Devinsky, O. *et al.*, 1995). In the rat, input to Sm originates primarily from trigeminal cells at the junction of the caudalis and interpolaris subnuclei of the trigeminal spinal tract nucleus and from trigeminal and cervical lamina I cells, as well as other cells in the spinal cord (Dado, R. J. and Giesler, G. J., Jr., 1990; Yoshida, A. *et al.*, 1992).

5.43.2.2 Indirect Nociceptive Pathways to the Thalamus

In addition to the STT, there are several polysynaptic pathways that may be involved in relaying nociceptive signals to the thalamus. First, the postsynaptic dorsal column pathway comprises dorsal horn neurons located primarily in laminae IV–VI and X whose axons ascend ipsilaterally in the superficial dorsolateral funiculus and deep dorsal columns and terminate in the ventral and rostral portions of the DCN (gracile and cuneate nuclei). These portions of the DCN have projections to motor-related regions of the brainstem rather than to VP (Brodal, A., 1982; Willis, W. D., 1985; Berkley, K. J. *et al.*, 1986). Although most of the neurons in this pathway respond only to nonnoxious cutaneous mechanical stimuli, some respond also to noxious stimuli. Some of the nociceptive neurons in this pathway convey visceral activity in the rat and possibly also in the primate (Al-Chaer, E. D. *et al.*, 1998; see also Villanueva, L. and Nathan, P., 2000). However, functional imaging studies of visceral pain in humans reveal a pattern of activation that does not appear consistent with the hypothesis that this pathway is important for visceral pain in humans (e.g., Strigo, I. A. *et al.*, 2003). Second, the spinocervicothalamic tract comprises dorsal horn neurons whose axons ascend ipsilaterally in the dorsolateral funiculus and terminate in the lateral cervical nucleus that is located at the level of C1-2 just lateral to the superficial dorsal horn (Boivie, J., 1983). The neurons of the lateral cervical nucleus project to the contralateral VP via the medial lemniscus. This pathway is prominent in the cat and raccoon but very small in the primate. Some of the neurons in this pathway respond to nociceptive stimuli although most respond only to innocuous stimuli (Kajander, K. C. and Giesler, G. J., Jr., 1987; Downie, J. W. *et al.*, 1988). Third, evidence obtained in the rat indicates that spinal input to a dorsal reticular region in the caudal medulla is relayed by way of a portion of the ventromedial nucleus to layer 1 of widespread regions of the frontal cortex (Desbois, C. *et al.*, 1999; Desbois, C. and Villanueva, L., 2001). This region also has a descending projection to the deep dorsal horn of the spinal cord. Modulation of activity, such as those associated with alerting responses, is suggested as a potential function, but whether this pathway exists in primates and humans is unknown. Fourth, a spinoreticulothalamic pathway (paleospinothalamic tract) was hypothesized long ago to accommodate clinical observations made in patients with thalamic pain syndrome (see below). Modern evidence indicates that spinal terminations in the brainstem reticular formation do not overlap with the locations of cells that project to thalamus, except within the PB (Blomqvist, A. and Berkley, K. J., 1992). The PB receives contralateral spinal input and ipsilateral trigeminal input that originates mainly from lamina I but also from lamina V cells. There is only a crude topography, and although there is considerable anatomical overlap with ascending homeostatic afferent input from the nucleus of the solitary tract, evidence in the rat indicates that nociceptive neurons are mainly modality selective (Bernard, J. F. and Besson, J. M., 1990). In primates, PB projects mainly to VMb in the thalamus, as well as to hypothalamus and amygdala, but in rats, it projects more broadly within medial thalamus and to various cortical regions associated with autonomic control.

5.43.3 Comparative Physiological Findings

The previous section described the pathways and thalamic termination sites of spinal and trigeminal neurons that include nociceptive neurons. On this basis, one would expect to find neurons in the

thalamic termination sites that would also respond to noxious inputs, and this is particularly the case for the regions receiving inputs from lamina I. There have indeed been many reports of nociceptive neurons in lateral, posterior, and medial areas of the thalamus. However, it should be kept in mind that the existence of neurons responding to noxious stimuli in a given region of thalamus does not necessarily signify that the region is involved in mediating the sensations of pain that would be expected to be elicited by noxious stimuli giving rise to the noxious responses. For example, the responses could be related to arousal, attentional, and motor consequences of the noxious stimulus. The following section will summarize the physiological findings reported for each of the main thalamic regions receiving nociceptive inputs.

5.43.3.1 Ventroposterior Nuclei

As mentioned earlier, the VPL and VPM are the main thalamic targets for innocuous tactile information ascending via the medial lemniscus from the DCN and principal trigeminal nucleus. It is thus not surprising that most of the neurons in this region respond exclusively to innocuous low-threshold mechanical cutaneous inputs. These neurons are organized in a high-resolution somatotopic fashion and project primarily to areas 3b and 1 of primary somatosensory (SI) cortex. There is an anterior and dorsally located shell that contains neurons responding to deep, muscle and joint afferent inputs, and this proprioceptive information is relayed to areas 3a and 2 of SI cortex (Kaas, J. H. *et al*., 1984; Jones, E. G., 1990).

It is generally considered that VP is the main relay nucleus for nociceptive inputs involved in mediating the sensory aspects of pain (localization and intensity discrimination) (Melzack, R. and Casey, K. L., 1968; Willis, W. D., 1985), since it receives STT inputs (primates and rodents, but not carnivores) and projects to the somatotopically organized SI cortex. Indeed, there have been many reports of nociceptive neurons within VP in the primate and rodent. In the monkey, about 10% of the neurons are nociceptive and most of these are of the wide dynamic range (WDR – responding to both LTM inputs and nociceptive inputs) type (Figure 2) (Willis, W. D., 1985; Apkarian, A. V. and Shi, T., 1994; Willis, W. D. and Westlund, K. N., 1997). They usually have moderately large receptive fields (e.g., more than half of the face or arm), and these are organized in a crude somatotopic manner roughly corresponding to the somatotopy of the intermingled LTM neurons (Willis, W. D. and Westlund, K. N., 1997). In the monkey, these neurons are concentrated in the posterior part of VP and near the major fiber laminae, consistent with the predominant location of the terminations of the STT and TTT axons of lamina V neurons (Applebaum, A. E. *et al*., 1979; Boivie, J., 1979; Kenshalo, D. R., Jr. *et al*., 1980; Casey, K. L. and Morrow, T. J., 1983; Gingold, S. I. *et al*., 1991; Bushnell, M. C. *et al*., 1993). Anatomical studies have provided evidence suggesting that the nociceptive neurons project to areas 3b and 1 of SI cortex. Interestingly, these studies suggest that the cortical terminations of these nociceptive neurons are in the most superficial layers of cortex in contrast to the VP LTM neurons whose axons terminate in the middle layer of cortex (Rausell, E. *et al*., 1992; Shi, T. *et al*., 1993), indicating a possible modulatory role for these nociceptive inputs. Electrophysiological studies have confirmed that some of these WDR neurons within VP can be antidromically activated from areas 3b and 1 of SI (Kenshalo, D. R., Jr. *et al*., 1980). Curiously, visceral noxious stimuli activate not only VP WDR neurons but also LTM neurons and do not appear to be somatotopically organized (Chandler, M. J. *et al*., 1992; Al-Chaer, E. D. *et al*., 1998).

Species differences: In the rat, nociceptive-specific (NS) and WDR nociceptive cells have been reported throughout VP intermixed in a roughly topographic manner with the LTM neurons (Guilbaud, G. *et al*., 1980). The receptive fields of these nociceptive neurons are generally quite large and often bilateral. Some receive convergent visceral input. In rats with experimentally induced arthritis or neuropathies, increased numbers of WDR VP cells that project to the sensorimotor cortex have been reported (Guilbaud, G. *et al*., 1990). In contrast to the primate and rodent, in the cat, there are virtually no nociceptive cells within VP proper. However, NS and WDR nociceptive neurons in this species can be found in the dorsal and ventral aspects of VP, the ventral aspect of VMb and VPI. These are the regions where STT and TTT terminations occur (see above). The nociceptive neurons within this shell-like region are organized in a crude mediolateral topographic pattern in parallel (but not in register) with the somatotopy of the adjacent VP. A portion of these neurons receive convergent input from skin, muscle, viscera, tooth pulp, or cranial vasculature (Davis, K. D. and Dostrovsky, J. O., 1988; Bruggemann, J. *et al*., 1994). Some of these neurons have been shown to project to area 3a of SI, SII, and/or anterior cingulate cortex (Yasui, Y. *et al*., 1988; Craig, A. D. and Dostrovsky, J. O., 2001).

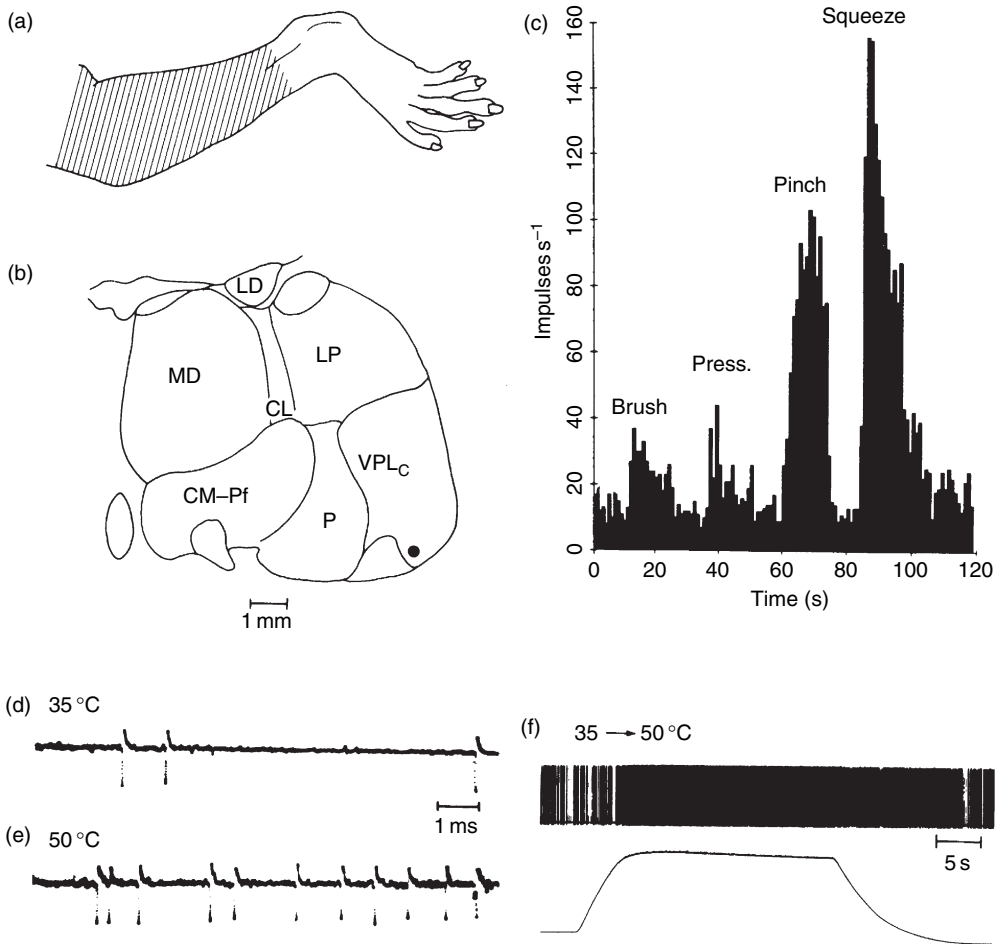

Figure 2 Example of responses of a wide-dynamic-range (WDR) neuron in ventroposterior nuclei (VP). The receptive field on the leg is shown in (a). The location of the recording site in VPLc (VP) is indicated in (b). The histogram (c) shows the responses to graded intensities of mechanical stimulation. This neuron also responded to noxious thermal stimulation (d, e, and f). Modified with kind permission from Kenshalo, D. R., Jr., Giesler, G. J., Jr., Leonard, R. B., and Willis, W. D. 1980. Responses of neurons in primate ventral posterior lateral nucleus to noxious stimuli. J. Neurophysiol. 43, 1594–1614.

5.43.3.2 Ventroposterior Inferior Nucleus

The neurons in the region located immediately inferior (ventral) to VPL and VPM (VPI) project to SII (Krubitzer, L. *et al.*, 1995) and to retroinsular (vestibular) cortex. Some of the neurons in this region are excited by nociceptive inputs (Figure 3). These WDR and NS neurons are arranged in a topographic representation within this region in the monkey (Apkarian, A. V. and Shi, T., 1994).

5.43.3.3 Posterior Thalamus and Posterior Part of the Ventromedial Nucleus

The posterior thalamus has frequently been implicated in pain processing and has been shown in various species to contain nociceptive neurons (Albe-Fessard, D. *et al.*, 1985; Willis, W. D., 1985; Willis, W. D., Jr., 1997). Although it was formerly regarded as undifferentiated, more detailed and recent observations in monkeys and humans have described a distinct nucleus that has been termed VMpo. The VMpo has been shown to be the recipient of a major projection from lamina I STT and TTT neurons. In accordance with its lamina I inputs, it has been shown to contain NS and thermoreceptive neurons (Craig, A. D. *et al.*, 1994). Their responses are similar to those of lamina I STT and TTT neurons, and they have small receptive fields that are topographically organized in a rostrocaudal axis, in correspondence with the topographically organized terminations of the afferent inputs (Figure 4).

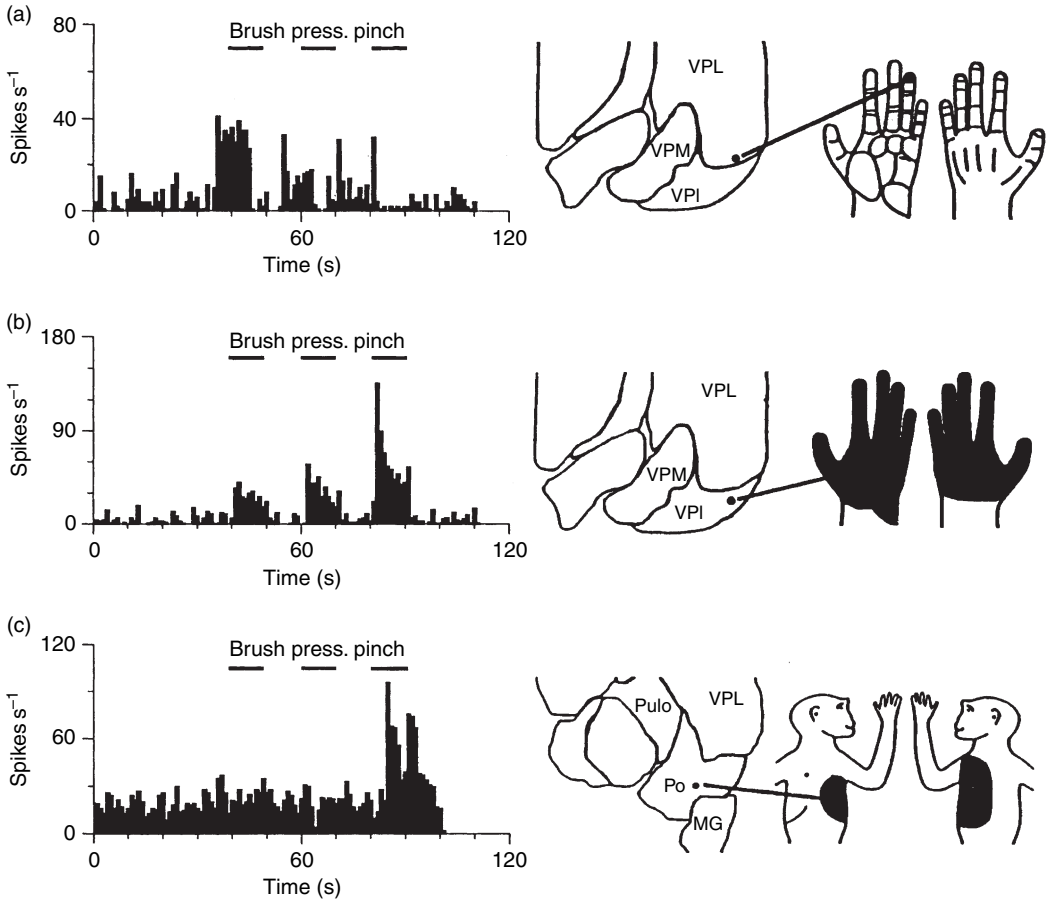

Figure 3 Example of responses of nociceptive neurons in ventroposterior inferior nucleus (VPI) and posterior complex (Po). Reproduced with kind permission from Apkarian, A. V. and Shi, T. 1994. Squirrel monkey lateral thalamus. I. Somatic nociresponsive neurons and their relation to spinothalamic terminals. J. Neurosci. 14, 6779–6795.

Neuronal recordings in awake monkeys in the presumed VMpo (originally assumed to be in VPM but subsequently re-interpreted from the original histology to be in VMpo (Craig, unpublished observations) revealed strong correlation between the neuronal activity and the behavioral detection of noxious and innocuous thermal stimuli applied to the face. Furthermore, lidocaine-induced block of activity in this region reduced the monkey's behavioral responses to these stimuli (Bushnell, M. C. *et al.*, 1993; Duncan, G. H. *et al.*, 1993).

Further support for the critical role of VMpo in relaying nociceptive and thermoreceptive information for perception of pain and temperature is the finding that it has a strong and topographic projection to the dorsal margin of the posterior insula (Craig, A. D., 2003), where preliminary fMRI observations in monkeys show strong activation with noxious stimuli (Craig, A. D., 2002). Furthermore, human imaging studies have consistently found this region of insular cortex to be activated by noxious and thermal stimuli. This rostrocaudally organized topography is distinct from the mediolateral topography observed in SII and in the adjacent parietal operculum (Disbrow, E. *et al.*, 2000). There is also a minor projection from VMpo to area 3a of SI cortex.

Species differences. In the cat and rat where there is no clearly differentiated nociceptive and thermoreceptive relay site in the Po, there are nevertheless nociceptive neurons, but they tend to have very large receptive fields and are not arranged in a clear somatotopic fashion (Poggio, G. F. and Mountcastle, V. B., 1960; Carstens, E. and Yokota, T., 1980). This region does receive some lamina I inputs in the cat. In the rat, there is convergent STT input from laminae I and V to the posterior triangular nucleus, which projects to the region of SII and to the amygdala. It is possible that in the rat, nociceptive inputs also arise

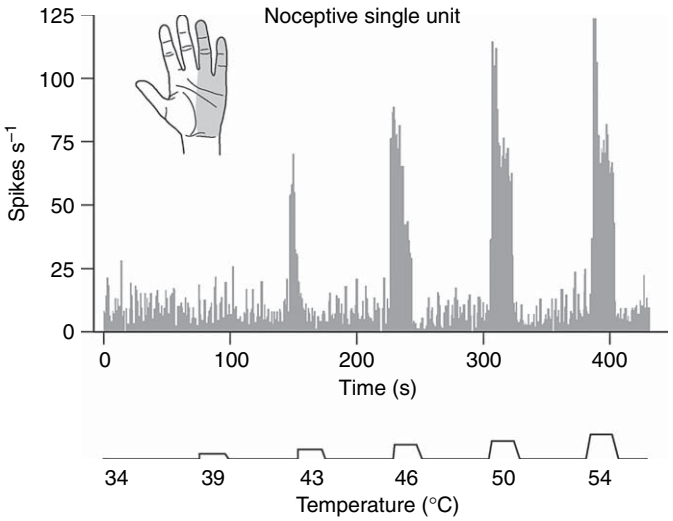

Figure 4 Example of the responses of a posterior part of the ventromedial (VMpo) nociceptive neuron. The histogram shows the graded responses of a single nociceptive-specific neuron to noxious heat pulses applied with a thermode applied to the receptive field on the contralateral ulnar hand. Adapted with kind permission from Craig, A. D., Bushnell, M. C., Zhang, E. -T., and Blomqvist, A. 1994. A thalamic nucleus specific for pain and temperature sensation. Nature 372, 770–773.

via a descending corticothalamic route (Diamond, M. E. *et al.*, 1992; Berkley, K. J. *et al.*, 1993). Furthermore, there is no direct projection to the portion of insular cortex homologous to that targeted by VMpo in the primate. The part of Po dorsal to VP in the cat, where some nociceptive neurons have been reported (Hutchison, W. D. *et al.*, 1992; Bruggemann, J. *et al.*, 1994), projects to area 5a (Jones, E. G., 1985). Nevertheless, in both the cat and the rat, there exists a narrow region along the ventral aspect of VMb that contains nociceptive and viscerоceptive neurons and projects to the insular cortex adjacent to the gustatory cortex (Yasui, Y. *et al.*, 1991; Clasca, F. *et al.*, 1997; Norrsell, U. and Craig, A. D., 1999).

5.43.3.4 Intralaminar Nuclei

As described earlier, several regions in medial thalamus receive direct inputs from the spinal cord and the trigeminal nucleus, but there are also indirect inputs to these regions from the brainstem, and in particular from the PB.

Neurons responding to noxious electrical, mechanical, or heat stimuli have been recorded throughout the intralaminar thalamus, in particular in CL and CM–Pf. Most of these recordings have been obtained in anesthetized rats and cats although some recordings have been performed in monkeys (Albe-Fessard, D. *et al.*, 1985; Bushnell, M. C. *et al.*, 1993; Bruggemann, J. *et al.*, 1994). Most of the nociceptive neurons in this region have large receptive fields that can be bilateral. Studies employing graded natural stimuli have revealed that some of the cells can code for stimulus intensity. Although natural stimulation was used in only some studies, cells with graded responses to noxious heat have been observed. In particular, a study in the awake monkey by Bushnell M. C. and Duncan G. H. (1989) reported the existence of nociceptive neurons in the CM–Pf and CL region that responded in a graded fashion to noxious thermal stimuli applied to the face (Figure 5). It is possible that the responses of at least some of these neurons may be related to attention and arousal rather than to perception of pain. It is interesting that many intralaminar neurons have been shown to respond to eye movements (Schlag, J. and Schlag-Rey, M., 1986), which is consistent with the termination of ascending inputs from the cerebellum and the superior colliculus. Indeed, it has been proposed that this region plays a role in gaze orientation (Jones, E. G., 1985).

5.43.3.5 Medial Dorsal Nucleus

As mentioned earlier, Craig and colleagues have recently described a direct lamina I input to the MDvc in the monkey. A particular interesting feature of this projection is that the MDvc contains neurons that project to the anterior cingulate cortex (Craig, A. D. and Zhang, E.-T., 1996), a region

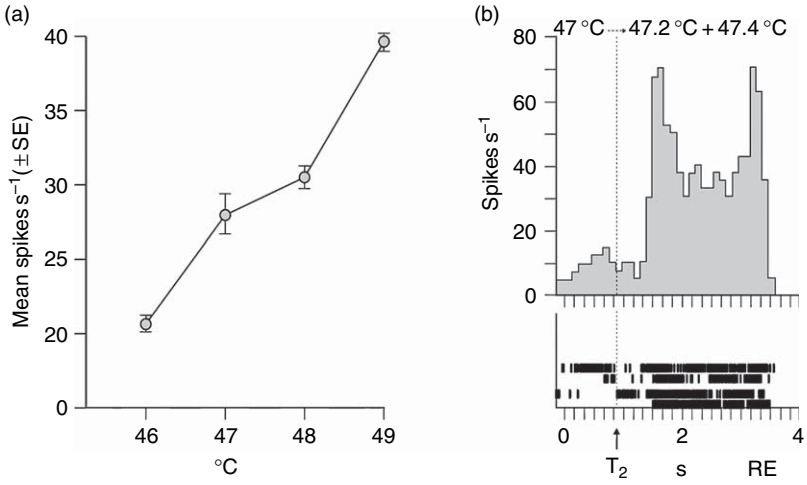

Figure 5 Responses of a neuron in posteromedial thalamus of an awake monkey to noxious thermal stimuli to the face. (a) The mean firing rate to increasing temperatures. (b) A peristimulus histogram with associated dot raster display showing increased firing when the temperature increased from 47 °C to 47.2 °C or 47.4 °C. In this particular example, the monkey did not respond until the end of the trial (RE button release). Adapted with kind permission from Bushnell, M. C. and Duncan, G. H. 1989. Sensory and affective aspects of pain perception: is medial thalamus restricted to emotional issues. Exp. Brain Res. 78, 415–418.

frequently implicated in pain. There is only very limited information regarding the properties of the neurons in MDvc; however, preliminary studies in anesthetized monkeys indicate that it contains a discrete group of NS neurons with large, sometimes bilateral receptive fields (Craig, A. D., 2003). Furthermore, this study reports that their spontaneous firing can be inhibited by innocuous thermal (cool, warm) stimuli. This phenomenon could provide an explanation for the well-known cold-induced inhibition of pain and the thermal grill illusion of pain (see below). It is possible that some of the recordings of nociceptive neurons in medial thalamus in the study of Bushnell M. C. and Duncan G. H. (1989) mentioned above may also have included neurons located in MDvc.

Species differences. Whereas in the monkey (and presumably the human), the STT and the TTT project to MDvc, in the cat and the rat, there is a projection that originates mainly in lamina I to the developmentally related Sm. Several studies have reported the existence of NS neurons in Sm in the rat (Dostrovsky, J. O. and Guilbaud, G., 1988; Coffield, J. A. and Miletic, V., 1993; Kawakita, K. *et al.*, 1993). Receptive fields are generally quite large and some have inputs from deep tissues. In the Freund's adjuvant-induced arthritic rat, many Sm cells were found to respond to joint movements, which are normally not effective in activating the Sm neurons (Dostrovsky, J. O. and Guilbaud, G., 1988). Various studies in the rat that have examined the effects of lesioning or electrically and chemically induced excitation of Sm have provided evidence for a role of Sm and its cortical target VLO in the activation of descending antinociceptive pathways by way of the periaqueductal gray (PAG) (Roberts, V. J. and Dong, W. K., 1994; Zhang, S. *et al.*, 1998). Although it has been shown in the cat that there is also a projection from innocuous thermoreceptive cool lamina I STT neurons in addition to the NS neurons (Craig, A. D. and Dostrovsky, J. O., 2001), neurons excited by cooling stimuli have not been found. It is possible, however, that inputs from these neurons may provide a basis for the cold-induced inhibition of nociceptive processing, similar to MDvc of the primate (Ericson, A. C. *et al.*, 1996).

5.43.4 Direct Physiological Evidence in Humans

Functional stereotactic surgery for the treatment of chronic pain or tremor provides a unique opportunity to record and stimulate in the thalamus of awake patients. There have been several studies that have provided information of interest in terms of furthering our understanding of the role of thalamus in pain and these are described below.

5.43.4.1 Nociceptive Neurons

Lenz and colleagues have searched for neurons in VP (often termed Vc in humans) and the immediately adjacent posterior and inferior region of thalamus. Although most of the neurons in Vc respond only to nonnoxious mechanical stimulation of the skin (LTM neurons), they reported that some neurons also had an increased response to noxious mechanical stimuli and some responded weakly to noxious or innocuous thermal stimuli in addition to innocuous tactile stimuli (i.e., WDR neurons) (for review, see Lenz, F. A. and Dougherty, P. M., 1997; Lee J. *et al.*, 1999). These WDR neurons were primarily located in the posteroinferior portion of VP. In the adjoining posteroinferior area, which includes VMpo (Blomqvist, A. *et al.*, 2000), they found NS neurons that responded to noxious heat but no LTM neurons (Lenz, F. A. *et al.*, 1993a). Although nociceptive neurons have frequently been reported in medial thalamus of anesthetized animals, there have only been a few old reports of neurons responding to noxious stimuli in awake human medial thalamus. It is difficult to evaluate these old reports since few details were provided and more recent studies have not been able to confirm the findings (Lenz, F. A. *et al.*, 1997). However, there have been very few opportunities to record from neurons in medial thalamus, and the number of neurons that can be tested with noxious stimuli in the awake patient is limited, and this may account for the lack of definitive evidence.

5.43.4.2 Innocuous Cooling-Responsive Neurons

Neurons responding selectively to innocuous cooling of the skin have been found in the human thalamic region located medial and posteroinferior to VP, which likely corresponds to VMpo (Davis, K. D. *et al.*, 1999). These neurons had discrete receptive fields on the contralateral body and responses similar to those of lamina I spinal and trigeminal neurons (Figure 6(a)). This finding is consistent with the findings in animals, where cooling-specific neurons have only been found

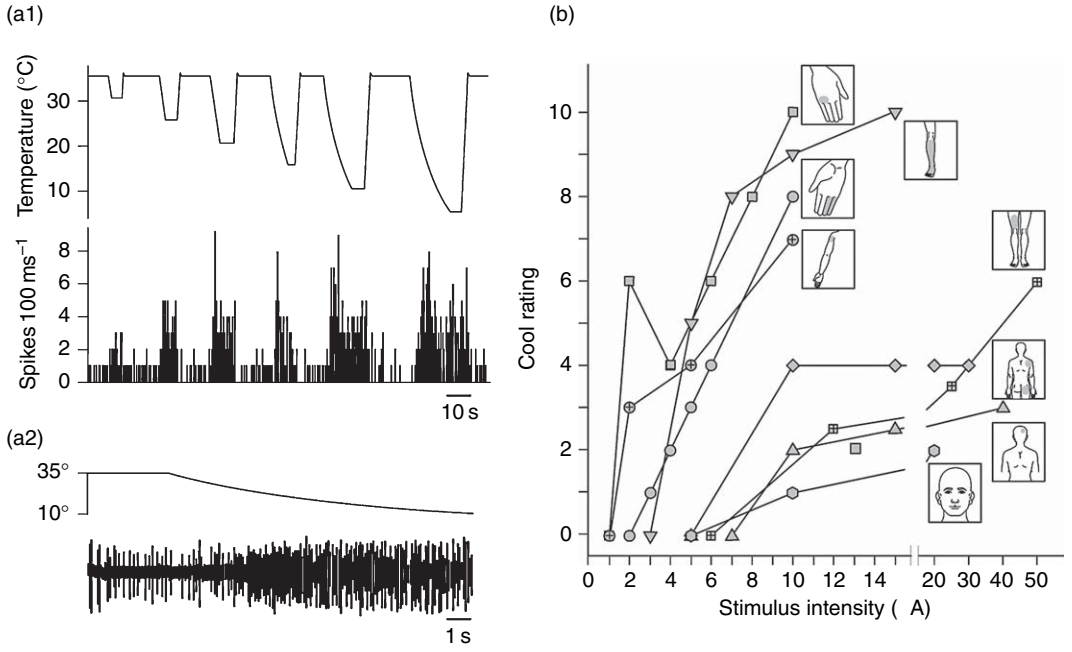

Figure 6 (a1) Recording from a single neuron in the presumed posterior ventromedial nucleus (VMpo) region in an awake patient showing responses to cooling stimuli applied to receptive field on the fifth digit. The top trace shows the temperature of the thermode with increasing cooling steps. The bottom trace is a histogram of the neuronal firing showing graded responses to the increasing cooling steps. (a2) Segment of raw trace of neuronal recording from (a1) showing response to first part of a cooling step. (b) Thalamic stimulation evoked cool sensations. Verbal ratings (0–10 scale) of the innocuous cool sensations evoked by threshold and suprathreshold intensities of thalamic microstimulation obtained in eight patients. Figurines adjacent to each line depict the location of the thalamic stimulation-evoked sensation at threshold. Reprinted with kind permission from Davis, K. D., Lozano, R. M., Manduch, M., Tasker, R. R., Kiss, Z. H., and Dostrovsky, J. O. 1999. Thalamic relay site for cold perception in humans. J. Neurophysiol. 81, 1970–1973.

in the cat medial VPM and in the monkey VMpo. Animal studies have also shown that cooling-specific neurons are found only in lamina I of the trigeminal medullary dorsal horn (nucleus caudalis) and spinal dorsal horn. Thus, the existence of cooling-specific neurons in the human VMpo is consistent with the evidence cited above that this region receives a major input from lamina I neurons. The close association of pain and temperature further supports an important role of VMpo in the relay of pain signals in the human.

5.43.4.3 Stimulation-Induced Pain and Temperature Sensations

The electrophysiological studies in human patients during stereotactic surgery provide a unique opportunity to determine the sensations evoked by electrical stimulation within the brain, since these are performed with the patient awake. As might be expected, electrical stimulation (1 s trains of 100–300 Hz) within VP and adjacent regions of the thalamus usually evokes innocuous paresthesia. These sensations, which can be elicited by low stimulus intensities (e.g., 2 μA), are perceived as originating from a small region of the contralateral side of the body (Figure 7). The projected fields are usually in register with the receptive fields of the neurons recorded at the stimulation site. Increasing the intensity of stimulation results in an increase in the perceived intensity of sensation and usually also with an increase in the projected field size, but although the sensation can be very

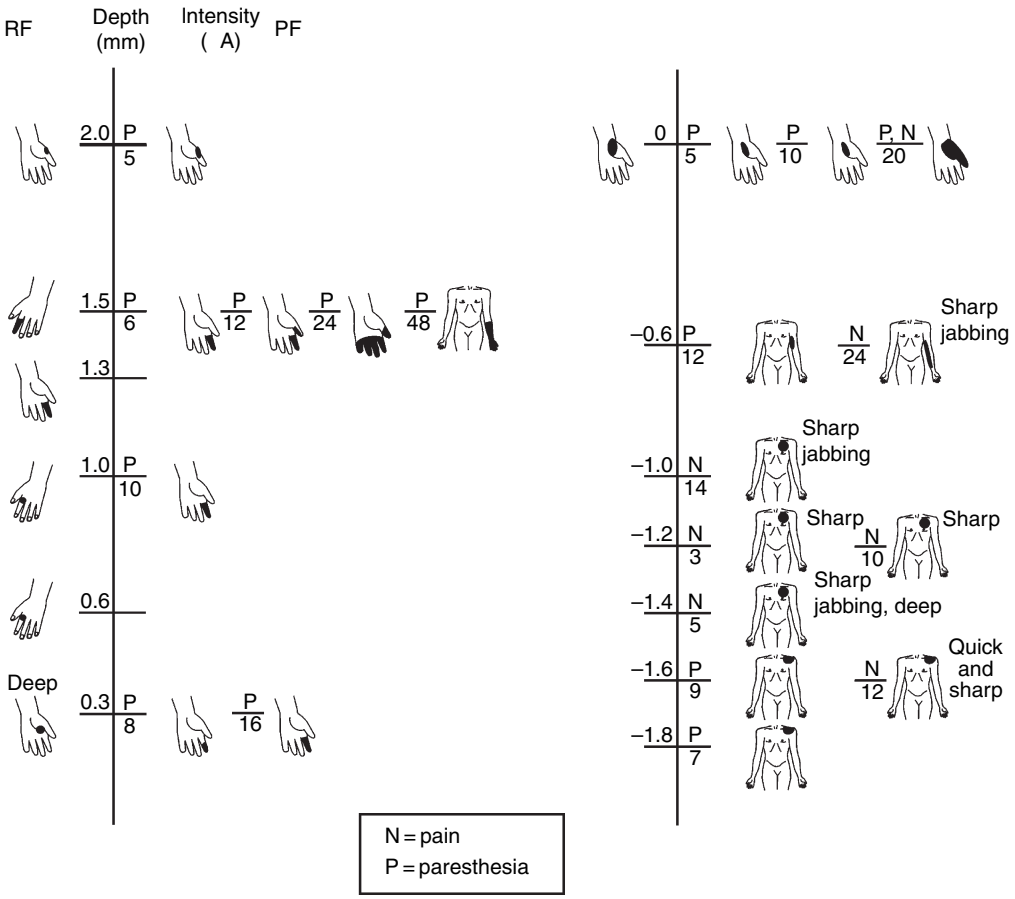

Figure 7 Stimulation-evoked pain in a chronic pain patient (causalgia left arm). The diagram shows a reconstruction of an electrode track through the ventrocaudal nucleus and on into the posteroinferior region, showing the locations of the receptive fields (RF) of the low-threshold mechanoreceptive neurons recorded at sites along the electrode track on the left of the vertical line and the projected fields (PF) induced by stimulation on the right side. The electrode track has been broken down into two contiguous segments. Depths of recordings are indicated in millimeters to the left of the line at each recording/stimulation site. While the electrode was in ventrocaudal nucleus (Vc), as evidenced by the low-threshold mechanoreceptive fields, stimulation induced nonpainful paresthesia (P). However, at the bottom of the Vc (0) and at deeper sites, stimulation induced painful sensations (N).

intense, it is not usually reported as painful. Nevertheless, stimulation at some sites in some patients is reported as eliciting a distinct painful and/or temperature sensation even at the threshold for sensation (Hassler, R. and Riechert, T., 1959; Halliday, A. M. and Logue, V., 1972; Tasker, R. R., 1984; Lenz, F. A. *et al*., 1993b; Davis, K. D. *et al*., 1996; Dostrovsky, J. O. *et al*., 2000). These sites are generally located near the posterior–inferior border of VP and extend several millimeters posterior, inferior, and medial to it (Figure 7). The incidence of sites where pain and/or thermal sensations can be evoked is much higher in the posteroinferior region than within VP (except in poststroke pain patients – see below). The sensations are always on the contralateral side of the body and can arise from a small region. The sensations are reported as being quite natural in contrast to the paresthesia (tingling or shock-like) sensations evoked within VP. There have been reports of cases where thalamic stimulation evoked pain arising from deep or visceral sites although these are rare (Lenz, F. A. *et al*., 1994; Davis, K. D. *et al*., 1995). Interestingly, Lenz and colleagues found that microstimulation within VP at sites where WDR neurons responding to noxious mechanical stimuli were found rarely elicited pain or temperature sensations, whereas at the sites in the region posteroinferior to VP where stimulation evoked pain, there was a high likelihood of finding nociceptive neurons (Lenz, F. A. and Dougherty, P. M., 1997). It seems likely that the sites in the region posteroinferior to VP where stimulation evokes pain and temperature are close to or in VMpo. It is also notable that at the sites where neurons responding selectively to cooling stimuli were found, microstimulation evoked cooling sensations arising from the same area of skin where the receptive fields of the neurons were located (Figure 6(b)). Increasing the stimulus intensity at such sites increased the intensity of the cold sensation (i.e., it felt colder).

There have been few studies of the effects of stimulation in medial thalamus. A few studies reported that stimulation in the posterior aspect of medial thalamus can evoke pain (Sano, K., 1979; Jeanmonod, D. *et al*., 1994). However, in most cases the stimuli were delivered from large-tipped electrodes and the sensations were only elicited at high current intensities, so current spread (e.g., to the STT) is an issue. Several more recent studies have failed to replicate these findings.

5.43.5 The Thalamus and Central Neuropathic Pain

5.43.5.1 Physiological Observations in Central Pain Patients

There have been many studies that have demonstrated the marked plasticity of the brain and in particular the alterations in neuronal properties and somatotopic organization at all levels of the somatosensory system subsequent to peripheral or central damage to the ascending pathways (Wall, J. T. *et al*., 2002). Although much less is known about the plasticity of the pain system, especially at the thalamic and cortical levels, it is reasonable to expect that marked changes will occur following damage to ascending nociceptive pathways. Indeed, there have been several animal studies that examined the effects of STT damage on thalamic physiology (Weng, H. R. *et al*., 2000; 2003). Studies in patients who have sustained deafferentation due, for example, to amputation or spinal cord injury provide evidence for plasticity (Lenz, F. A. *et al*., 1994; Davis, K. D. *et al*., 1998). For example, there is evidence suggesting expansion of the representation of intact regions into deafferented regions of VP thalamus. Micro-stimulation in such regions was found to evoke sensations arising from the phantom limb in amputees or to the deafferented body region in spinal injury patients (Lenz, F. A. *et al*., 1994; Davis, K. D. *et al*., 1998). Although these stimuli usually resulted in nonpainful paresthesia rather than pain, these types of changes may be involved in the development of chronic pain in these types of patients. Of particular interest have been the findings of two studies that found changes in the stimulation-evoked sensations in poststroke pain and some other types of chronic central pain patients. The incidence of stimulation sites in VP where stimulation evoked sensations in such patients was markedly elevated (Lenz, F. A. *et al*., 1998; Dostrovsky, J. O. *et al*., 2000). In addition, there was an increase in the number of sites in the posteroinferior region where pain sensations were evoked and a decrease in sites where innocuous thermal stimuli were evoked (Figure 8). These findings provide further evidence suggesting that there have been alterations in the thalamic and cortical processing of somatosensory inputs leading to increased perception of pain. It is interesting, however, that deep brain stimulation within thalamus (Siegfried, J., 1987; Kupers, R. C. and Gybels, J. M., 1993) can alleviate the pain in some of these chronic pain patients, possibly by disrupting the pathological patterns and balance of activity in these regions.

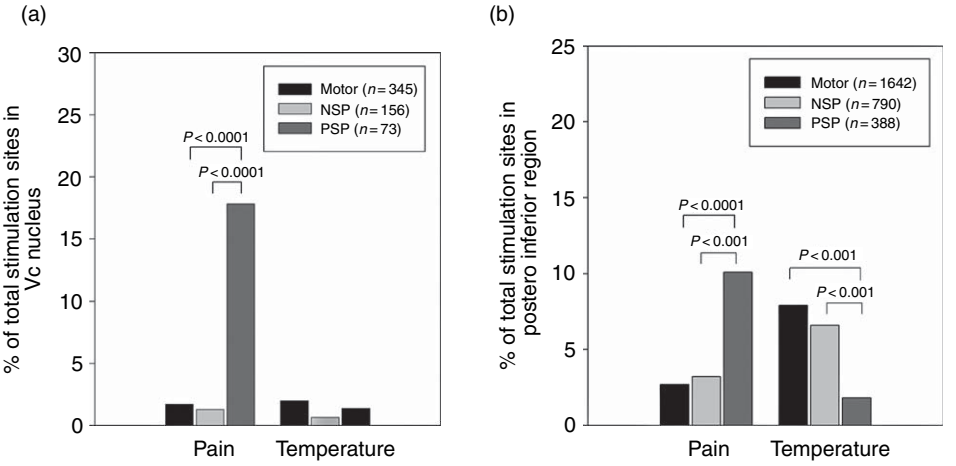

Figure 8 Bar graphs showing the incidence of sites in the ventrocaudal nucleus (a) and the posteroinferior region (b) where stimulation evoked sensations of pain or innocuous temperature in movement disorder patients (Motor), chronic nonpoststroke pain patients (NSP), and poststroke pain patients (PSP). Reprinted with kind permission from Dostrovsky, J. O., Manduch, M., Davis, K. D., Tasker, R. R., Lozano, A. M. 2000. Thalamic Stimulation-Evoked Pain and Temperature Sites in Pain and Non-pain Patients. In: Proceedings of the 9th World Congress on Pain (*eds*. M. Devor, M. C. Rowbotham, and Z. Wiesenfeld-Hallin), pp. 419–425. IASP Press.

5.43.5.2 Thalamic Bursting Activity

Thalamic neurons switch to a bursting mode when they are hyperpolarized. This bursting activity is generated by activation of low-threshold T-type calcium channels that give rise to a calcium spike and a burst of sodium channel-generated action potentials (so-called LTS bursting). This bursting activity is generally only observed during sleep. However, recordings in medial and lateral thalamus of chronic pain patients during the awake state revealed the existence of neurons firing in typical calcium spike-mediated bursts (Lenz, F. A. *et al*., 1989; Jeanmonod, D. *et al*., 1993; Lenz, F. A. *et al*., 1994). It was proposed that this activity may be related to the patients' chronic pain and in fact may mediate the spontaneous pain in these patients (Lenz, F. A. and Dougherty, P. M., 1997; Llinas, R. R. *et al*., 1999). However, similar LTS firing in similar regions of thalamus can also be observed in patients without pain and thus is not specific to pain (Jeanmonod, D. *et al*., 1996; Radhakrishnan, V. *et al*., 1999). More recently, Llinas R. R. *et al*. (1999) have proposed that LTS bursting in thalamus may be the cause of many different neurological diseases including chronic pain and have termed this condition thalamic dysrhythmia. Nevertheless, the role of LTS bursting in chronic central pain remains unclear.

It has been proposed that central neuropathic pain may be mediated by reduced GABAergic inhibition in the thalamus (Roberts, V. J. and Dong, W. K., 1994). Studies in the primate have found that following chronic cervical rhizotomy there is a downregulation of thalamic $GABA_A$ receptors (Rausell, E. *et al*., 1992), providing some support for this suggestion. On the other hand, several positron emission tomography (PET) studies have obtained evidence suggesting that chronic neuropathic pain is associated with decreased blood flow, suggesting decreased activity (Apkarian, A. V. *et al*., 2005).

5.43.5.3 Effects of Thalamic Lesions on Pain

There have been many studies since the original pioneering studies of Dejerine and Roussy and Head and Holmes which have documented that strokes affecting the lateral thalamus can lead to central pain (poststroke pain and thalamic pain syndrome) (Pagni, C. A., 1998). In addition, infarcts and lesions that involve the posteroinferior region can also result in analgesia and thermanesthesia (Head, H. and Holmes, G., 1911; Hassler, R. and Riechert, T., 1959; Hassler, R., 1970; Tasker, R. R., 1984). Lesions have been purposefully made in medial thalamus of chronic pain patients for relief of their pain (Gybels, J. M. and Sweet, W. H., 1989). However, such procedures are rarely undertaken at the present time as most neurosurgeons do not believe that they are effective. It is possible, however, that in some of

the reported successes the lesions may have included MDvc and/or VMpo (Jeanmonod, D. *et al.*, 1994; Lenz, F. A. and Dougherty, P. M., 1997). Interestingly, lesions in medial thalamus that spare the lateral thalamus and STT do not appear to cause central pain (Bogousslavsky, J. *et al.*, 1988).

5.43.5.4 The Thalamic Pain Syndrome

The poststroke central (thalamic) pain (CPSP) syndrome was first recognized by Dejerine and Roussy, and it has been comprehensively analyzed clinically by Head H. and Holmes G. (1911), Riddoch G. and Critchley Mc. D. (1937), Schott B. *et al.* (1986), Boivie J. (1994), Pagni C. A. (1998), and others. The first patients had lesions confined to the thalamus, and so the syndrome was first called thalamic pain. However, patients with central pain have lesions that interrupt the ascending lateral STT – lamina I – spinothalamocortical pathway by way of VMpo to the dorsal posterior insula at any level (Schmahmann, J. D. and Leifer, D., 1992; Pagni, C. A., 1998; Craig, A. D., 2003). Such lesions produce loss of pain and temperature sensation, but in about half of such cases, this disruption results, immediately or after a variable delay, in the paradoxical appearance of ongoing pain in the deafferented region. Head and Holmes inferred that this meant that pain sensation occurred in the thalamus, but we now know that the thalamus serves mainly as a relay for activity ascending to the cortex. This syndrome likely results from disruption of the interactions at cortical and subcortical levels between components of the pain processing network. One such interaction is the inhibition caused by cooling on pain, and it has been suggested that interruption of this interaction could cause central pain by disinhibition (Craig, A. D., 1998). The suggestion is based on similarities with the thermal grill illusion of pain, in which reduced activity in cooling-specific lamina I STT neurons can unmask the cold-activated burning pain elicited by polymodal nociceptive lamina I STT neurons (HPC) in the anterior cingulate cortex. A study of thermal sensation in a central pain patient directly supports that hypothesis (Morin, C. *et al.*, 2002). A recent imaging study of a central pain patient suggested that the posterolateral thalamic lesion did not involve VMpo but that conclusion was incompatible with the patient's loss of thermal sensation (cf. Craig, A. D. *et al.*, 2000; Montes, C. *et al.*, 2005). The indirect ascending nociceptive input to the medial thalamus by way of the PB may also play a role in central pain.

5.43.6 Pharmacology

The pharmacology of thalamic nociceptive neurons has not been extensively studied. However, it is reasonable to assume that they share many common features with those of other thalamic neurons about which much more is known. The two most important transmitters are glutamate and GABA (McCormick, D. A., 1992; Steriade, M. *et al.*, 1997; Sherman, S. M. and Guillery, R. W., 2001). Glutamate is released by the ascending axons of medial lemniscal and STT and TTT pathways to excite thalamocortical neurons. The released glutamate acts at both NMDA and non-NMDA (AMPA and/or kainate) ionotropic glutamate receptors. In the cat and primate, there are also many interneurons within the thalamus and these also receive glutamatergic inputs from these afferents that activate in addition to the ionotropic receptors and metabotropic glutamate receptors (Jones, E. G., 1985; Magnusson, K. R. *et al.*, 1987; Ericson, A. C. *et al.*, 1995; Blomqvist, A. *et al.*, 1996; Sherman, S. M. and Guillery, R. W., 2001). The thalamocortical neurons also receive a massive glutamatergic projection from layer 6 of the cortex, which activates both ionotropic and metabotropic receptors (Rustioni, A. *et al.*, 1983; Jones, E. G., 1987; Deschenes, M. and Hu, B., 1990; Eaton, S. A. and Salt, T. E., 1990; 1996; Salt, T. E. and Eaton, S. A., 1996). The thalamocortical neurons release glutamate at their cortical terminals (Kharazia, V. N. and Weinberg, R. J., 1994; Pirot, S. *et al.*, 1994).

GABA is the major inhibitory neurotransmitter in the thalamus, and the major source of these inputs is from the thalamic reticular nucleus (TRN). The TRN GABAergic neurons are topographically organized and receive excitatory inputs from collaterals of thalamocortical and corticothalamic neurons. In cats and primates, but not rats, there are also GABAergic interneurons within the thalamus (Houser, C. R. *et al.*, 1980; Rustioni, A. *et al.*, 1983; Jones, E. G., 1985; Steriade, M. *et al.*, 1997). The TRN produces both short- and long-latency inhibitory responses; the short-latency IPSPs are mediated by $GABA_A$ receptors, whereas the long-latency responses are mediated by the $GABA_B$ metabotropic receptors (Lee, S. M. *et al.*, 1994). Interestingly, activation of presynaptic glutamate metabotropic receptors reduces the release of GABA from the TRN receptors (Salt, T. E. and Eaton, S. A., 1995). Most of the studies of thalamic GABAergic

mechanisms have involved nonnociceptive neurons; however, studies in Pf have shown that thalamic nociceptive neurons receive inhibitory inputs from the TRN and are inhibited by GABA (Reyes-Vazquez, C. and Dafny, N., 1983; Jia, H. *et al.*, 2004), and microinjection of the $GABA_A$ antagonist bicuculline or agonist muscimol into Sm enhanced or depressed, respectively, the antinociception induced by the prior microinjection of morphine into the rat Sm (Jia, H. *et al.*, 2004). There is also recent evidence for modulation of $GABA_B$ receptors in VP and Po by noxious inputs (inflammation) (Ferreira-Gomes, J. *et al.*, 2004).

The thalamic relay neurons as well as the TRN and inhibitory interneurons also receive projections from serotoninergic neurons in the dorsal raphe nucleus, and norardrenergic and cholinergic neurons in the peribrachial region (see reviews by McCormick, D. A., 1992; Steriade, M. *et al.*, 1997). Their role in nociception is, however, unclear. There have been recent studies in the rat that have demonstrated an involvement of serotoninergic mechanisms in modulation of transmission through the Sm, and these may play a role in a pain modulatory system proposed to relay in Sm (Xiao, D. Q. *et al.*, 2005). There is also evidence that 5HT modulates nociceptive processing in the rat Pf (Harte, S. E. *et al.*, 2005). Several neuropeptides have also been identified in thalamic afferents and neurons. For example, tachykinins, cholecystokinin, and enkephalins have been identified in spinothalamic fibers ending in the rat and human thalamus and are presumably coreleased with glutamate, but their function is not known (Coffield, J. A. and Miletic, V., 1987; Gall, C. *et al.*, 1987; Hirai, T. and Jones, E. G., 1989; Battaglia, G. *et al.*, 1992; Nishiyama, K. *et al.*, 1995).

It is usually assumed that the analgesia produced by opiates results from an action at the spinal and brainstem levels. However, there is increasing evidence for a role of opioids also at thalamic and cortical levels, and thus, a direct depressant effect of opioids on thalamic and cortical nociceptive neurons may contribute to the opioid-induced analgesia. Opioid receptors and enkephalinergic terminals have been identified in the thalamus (Mansour, A. *et al.*, 1987; Miletic, V. and Coffield, J. A., 1988). Systemic morphine inhibits thalamic nociceptive neurons (e.g., Benoist, J. M. *et al.*, 1983), but this does not prove that effect is due to an action at the thalamic level. However, there have been studies that have shown that local application of opioid agents can depress the responses of thalamic nociceptive neurons (He, L. F. *et al.*, 1991; Coffield, J. A. and Miletic, V., 1993) and produce antinociception when microinjected into Sm (Yang, Z. J. *et al.*, 2002). Furthermore, the use of radiolabeled μ-opioid agonists with PET has shown high opiate receptor levels in the human thalamus (see review in Apkarian, A. V. *et al.*, 2005), and evidence for their involvement in endogenous pain modulation.

Glossary

dorsal columns A pathway carrying axons of fibers in the peripheral nerve through the posterior aspect of the spinal cord to the dorsal column nucleus at the posterior aspect of the medulla where they synapse and ascend through the medial lemnisus to the principal nucleus of thalamus. Classically, this pathway transmits low-threshold muscle and cutaneous afferents but recent studies demonstrate that afferents transmitting nociceptive, thermal, or visceral inputs are also transmitted.

nociceptive specific (NS) neurons Neurons responding only to stimuli which are noxious or painful.

wide dynamic range (WDR) neurons Neurons responding to stimuli across the intensive continuum into the painful or noxious range.

projected field in the somatosensory system A part of the body at which a sensation is evoked in response to stimulation of the central nervous system.

receptive field In the somatosensory system: skin region, stimulation of which can influence the discharge of the neuron under study

somatic sensory nuclear group of the thalamus Nuclei receiving input from the dorsal column nuclei, the spino- or the trigeminothalamic tract by either a direct or a transsynaptic route. Summary term for the specific somatosensory nuclei of the thalamus. Most commonly used taxonomy is for monkey thalamus: VPL (ventroposterolateral), VPM (ventroposteromedial), VPI (ventroposteroinferior) corresponding to humans: Vc (ventrocaudal, both medial and lateral). Adjacent, both posterior medial, to VPM ventral medial posterior (VMpo), a putative pain and temperature signaling nucleus may be located (Craig, A. D. *et al.*, 1994, cf. Willis, W. D., Jr. *et al.*, 2001, Graziano, A. and Jones, E. G., 2004; Lenz, F. A. *et al.*, 2004). VMpo may be located medial to ventral caudal portae (Vcpor), while intralaminar nuclei mostly a thin layer of neurons located medial to Vim, Vc, and Vcpor (see Figure 1(a)).

spinothalamic tract (STT) The pain and temperature signaling pathway from neurons in the spinal dorsal horn to the lateral and anterolateral funiculi of the spinal cord and the brainstem to the lateral, posterior, medial, and intralaminar nuclei of thalamus.

spinothalamocortical pathways Cortical areas which receive input from thalamic nuclei that themselves receive STT input. These thalamocortical connections include those from Vc to primary somatosensory and secondary somatosensory cortex, from Vcpor, Vcpc, and VMpo to parietal opercular, insular, and retroinsular cortex, and finally from the medial dorsal nucleus to anterior cingulate cortex.

sylvian fissure Also called lateral sulcus, the sylvian fissure separates the temporal lobe from the frontal and parietal lobes (see Figure 6, left – middle and lower levels). The insula is a cortical surface, which is located deep to the lateral fissure and parallel to the cortical surface on coronal and axial sections (Figure 6, middle and right). The frontal, parietal, and temporal opercula are folds of cortex that extend over the insula and meet each other over the insula. The sulcus between the frontal–parietal opercula and the temporal operculum is the sylvian fissure.

Talairach coordinates Initially developed for a specific stereotactic frame; based on one single brain; frequently used as common coordinate system; *x*: left–right, *y*: anterior–posterior, *z*: superior–inferior; the reference point (0, 0, 0) is the anterior commissure (Talairach, J. and Tournoux, P., 1988).

thalamus A subcortical gray matter structure characterized by reciprocal connections with the cortical mantle and by inputs from the periphery and nuclei of the brain, such as the pallidum.

5.44.1 Introduction

The dorsal column pathway and the spinothalamic tract (STT) are the two main somatosensory spinal tracts afferent to the thalamus. The dorsal column pathway is formed by the axons of low-threshold mechanoreceptors with cell bodies in the dorsal root ganglion. These axons terminate to the principal somatic sensory nucleus of the thalamus (human ventral caudal or Vc, monkey ventral posterior or VP) (Jones, E. G. *et al.*, 1982; Kaas, J. H. *et al.*, 1984; Lenz, F. A. *et al.*, 1988; Willis, W. D. and Coggeshall, R. E., 1991). The dorsal columns do contain a postsynaptic pain pathway signaling noxious visceral stimuli, which terminates in the Vc (Uddenberg, N., 1968; Rustioni, A. *et al.*, 1979; Willis, W. D., *et al.*, 1991; Al Chaer, E. D. *et al.*, 1996b). The STT is a pain pathway that originates from the spinal dorsal horn, and ascends in the anterolateral quadrant of the spinal cord before terminating in the thalamus (Willis, W. D., Jr. *et al.*, 2001). Stimulation of these thalamic nuclei in man reveals the psychophysical dimensions of these pathways which is the subject of this chapter.

5.44.2 The Spinothalamic Tract

Many neurons in the STT are characterized by their response to noxious or painful stimuli. Some of these respond to the somatic stimuli across the intensive continuum into the noxious range (WDR – wide dynamic range). These cells arise from both superficial (lamina I) and deep laminae of the dorsal horn (laminae IV–V) (Kumazawa, T. and Perl, E. R., 1978; Willis, W. D., 1985; Ferrington, D. G. *et al.*, 1987). Some neurons in the superficial dorsal horn respond only to different stimuli including noxious stimuli (nociceptive specific (NS) cells), cold (Kumazawa, T. and Perl, E. R., 1978; Willis, W. D., 1985; Ferrington, D. G. *et al.*, 1987; Craig, A. D. *et al.*, 1994), injection of histamine (itch – Andrew, D. and Craig, A. D., 2001; Craig, A. D., 2003b), or visceral stimuli (Craig, A. D., 2003a). The deep and superficial laminae of the dorsal horn project to the brain, respectively, through the ventral lateral (ventral STT) and the dorsal lateral spinal funiculi (dorsal STT) (Apkarian, A. V. and Hodge, C. J., 1989; Cusick, C. G. *et al.*, 1989; Ralston, H. J. and Ralston, D. D., 1992; Craig, A. D., 1998, 2003b; Price, D. D. *et al.*, 2003).

The population of neurons in the superficial dorsal horn responding only to noxious stimuli has led to the description of the STT as a structure signaling only pain – a labeled line (Perl, E. R., 1984; Willis, W. D., 1985). A recent version of this hypothesis suggests that the STT is a series of labeled lines for cool and itch, as well as pain that jointly reflect the internal state of the body (interoception) (Craig, A. D., 2003a; 2003b). In this view, pain is the emotion produced by disequilibrium of the internal state. An alternate view is that pain is signaled by WDR neurons which transmit a

graded signal, the strength of which might be decoded in the brain to identify the presence of a painful stimulus (Price, D. D. and Dubner, R., 1977; Willis, W. D., 1985; Price, D. D. *et al.*, 2003). This chapter examines recent evidence from stimulation of the human central nervous system as they impact these hypotheses.

One approach to identifying the pain pathway has been to stimulate the cord during cordotomy using paired-pulse stimulus parameters that selectively activate the axons arising in the superficial or deep laminae (Mayer, D. J. *et al.*, 1975). This interpulse threshold was more consistent with that of cells in the deep than the superficial dorsal horn (Price, D. D. and Mayer, D. J., 1975). The results suggest that the sensory aspect of pain is signaled through the axons in ventral STT which originate from the WDR neurons in the deep dorsal horn (Price, D. D. and Dubner, R., 1977; Dubner, R. *et al.*, 1989).

5.44.3 The Dorsal Column Pathway

The dorsal column pathway is formed by the axons of low-threshold mechanoreceptors that project through the dorsal column nuclei and medial lemniscus to the region of the principle somatic sensory nucleus (ventral caudal, Vc) (Jones, E. G. *et al.*, 1982; Kaas, J. H. *et al.*, 1984; Lenz, F. A. *et al.*, 1988; Willis, W. D. *et al.*, 1991). As shown in Figure 1 receptive fields are quite constant within a particular parasagittal plane in Vc. From medial to lateral planes, the sequence of neuronal cutaneous receptive fields progresses from intraoral through face, thumb, fingers (radial to ulnar), and arm to leg. Proximal parts of the limbs are represented dorsal to the corresponding digits (Lenz, F. A. *et al.*, 1988).

Substantial evidence demonstrates that the dorsal columns do contain a postsynaptic pain pathway signaling noxious visceral stimuli, rather than noxious somatic stimuli, which terminates in the VP (Uddenberg, N., 1968; Rustioni, A. *et al.*, 1979; Willis, W. D. *et al.*, 1991; Al Chaer, E. D. *et al.*, 1996b). This postsynaptic pathway has been demonstrated by infusion of neurotransmitter agonists/antagonists into the dorsal horn, which alters the response of neurons in the dorsal column nuclei to visceral stimuli. Furthermore, lesions of rat nucleus gracilis diminish the response of neurons in VP to visceral as well as cutaneous stimuli (Al-Chaer, E. D. *et al.*, 1997).

The cells of origin of this pathway are located just dorsal to the central canal, as demonstrated by antidromic invasion from nucleus gracilis (Al Chaer, E. D. *et al.*, 1996a), and by retrograde and anterograde tracer studies (Christensen, M. D. *et al.*, 1996). Retrograde tracer studies depositing marker in the nucleus gracilis (Christensen, M. D. *et al.*, 1996) label cell bodies of origin of the pathway in the medial base of the dorsal horn just above the central canal. Injection of tracer into this area resulted in fiber labeling of the dorsal column midline and in the medial aspect of the nucleus gracilis. Fibers originating in the thoracic cord terminate in the lateral part of nucleus gracilis and adjacent to the medial parts of nucleus cuneatus (Wang, C. C. *et al.*, 1999; Willis, W. D. *et al.*, 1999). Along with the STT, a major terminus of the postsynaptic dorsal horn pathway is the lateral thalamus.

5.44.4 Thalamic Nuclei

5.44.4.1 Lateral Thalamic Nuclei

The human principal sensory nucleus (Vc) (Hassler, R., 1959) is divided into a core area (equivalent to monkey VP, see Olszewski, J., 1952; Hirai, T. and Jones, E. G., 1989), posterior, and inferior regions. These two regions are defined relative to the most posterior and inferior cell with a response to nonpainful, cutaneous stimuli (cell 57 in Figure 1(b)). In the core, the majority of cells respond to innocuous, mechanical, and cutaneous stimulation. This latter area corresponds to the posterior and inferior subnuclei of Vc, which are ventral caudal portae (Vcpor), ventral caudal parvocellular nucleus (Vcpc) (Mehler, W. R., 1966), the posterior nucleus, and the magnocellular medial geniculate (Mehler, W. R., 1962; Mehler, W. R., 1966; Lenz, F. A. *et al.*, 1993b) (see Vc and Vcpor in sagittal section in Figure 1(a)). Studies of patients at autopsy following lesions of the STT show terminations in all this nuclei (Bowsher, D., 1957; Mehler, W. R., 1966; Mehler, W. R., 1969). This area includes the ventral medial nucleus – posterior part (VMpo), which may receive STT inputs and may signal pain and temperature (Craig, A. D. *et al.*, 1994; Blomqvist, A. *et al.*, 2000; cf. Willis, W. D., Jr. *et al.*, 2001; Graziano, A. *et al.*, 2004). The physiology recapitulates this anatomy.

Cells in Vc responding to painful and thermal stimuli are of several types, including WDR and NS cells responding to painful thermal and mechanical stimuli (see figure 2 in Lee, J.-I. *et al.*, 1999). Figure 2(a) demonstrates the response of a single neuron with WDR properties to a painful 45 °C

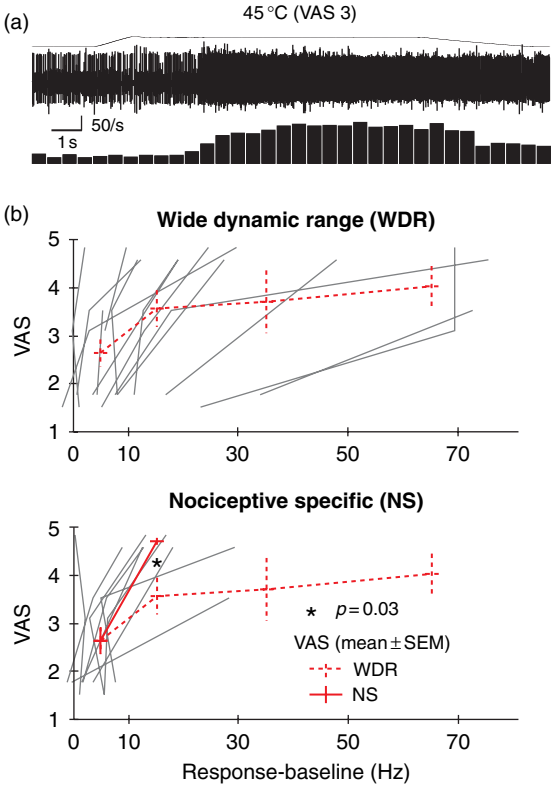

Figure 2 Activity of neurons in the region of Vc (ventrocaudal) responding to painful thermal stimuli. The response to nonpainful and painful heat/mechanical stimuli applied within the receptive field (RF) (Lenz, F. A. *et al.*, 1994b; Lee, J.-I. *et al.*, 1999) is compared with the visual analog scale of intensity (VAS) evoked by the same stimulus. (a) The response of a cell wide dynamic range (WDR) to painful heat. (b) VAS and firing rates for the response to painful stimuli are plotted for nociceptive (NS) cells which respond only to painful stimuli and WDR neurons, which respond in a graded fashion to nonpainful and painful stimuli. Average and one standard deviation scores by decade to 20 Hz and by 30 Hz steps from 20 to 80 Hz were compared by Mann–Whitney *U* test. Reprinted from Lenz F. A., Ohara, S., Gracely, R. H., Dougherty, P. M., and Patel, S. H. 2004. Pain encoding in the human forebrain: binary and analog exteroceptive channels. J. Neurosci. 24, 6540-6544 with permission ©2004 by the Society for Neuroscience).

stimulus. Responses to painful stimuli were characterized by the mean firing rate during painful stimulation, recorded through the microelectrode (Figure 2(b), *x*-axis), and by visual analog scale of intensity (VAS) ratings of microstimulation-evoked pain (*y*-axis). Some low-threshold cells respond to nonpainful mechanical and cold stimuli (Figure 2) (Lenz, F. A. *et al.*, 1993a; Lenz, F. A. and Dougherty, P. M., 1998; Lee, J.-I. *et al.*, 1999). Cells in the core and posterior region respond only to noxious heat stimuli (Lenz, F. A. *et al.*, 1993a; 2004) and to noxious cold stimuli (Davis, K. D. *et al.*, 1999).

Nociceptive cells in Vc appear to signal pain based on temporary lesioning and stimulation studies. Blockade of the activity in this region by injection of local anesthetic into monkey VP, corresponding to human Vc (Hirai, T. *et al.*, 1989), significantly interferes with the monkey's ability to discriminate temperature in both the innocuous and noxious range (Duncan, G. H. *et al.*, 1993). Stimulation within Vc and the regions posterior and inferior to it can evoke the sensations of pain (Hassler, R. and Reichert, T., 1959; Willis, W. D., 1985; Dostrovsky, J. O. *et al.*, 1991; Lenz, F. A. *et al.*, 1993b) and temperature (Lenz, F. A. *et al.*, 1993b; Davis, *et al.*, 1999).

The largest study of stimulation-evoked pain and temperature responses examined results of threshold microstimulation of the region of Vc in 124 thalami (116 patients), as summarized in Figure 3. The location of pain and temperature responses is defined relative to the posterior and inferior borders of the principal somatic sensory nucleus (Vc). Warm sensations were evoked more frequently in the posterior region (5.7%) than in the core (2.3%). Otherwise the proportions were not significantly different for cool or pain sensations between the core or the posterior region or both (cool 2.5%, 2.2%; pain 2.8%, 4.1%).

Figure 1 Map of receptive and projected fields for trajectories in the regions of the Vc (ventrocaudal) in a single patient (number 193.97). (a) Positions of the trajectories relative to nuclear boundaries as predicted radiologically from the position of the anterior commissure–posterior commissure (AC–PC) line. The AC–PC line is indicated by the horizontal line in the panel; the trajectories are shown by the two oblique lines. The positions of nuclei are inferred from the AC–PC line and therefore are only an approximate indicator of nuclear location. Scale as indicated. Abbreviations defined in the text. (b) Location of the cells, stimulation sites, and trajectories (P1 and P2) relative to the AC–PC line (a solid line) and the ventral border of the core of Vc (a dotted line). The locations of stimulation sites are indicated by ticks to the left of the trajectory; the locations of the cells are indicated by ticks to the right of the trajectory. Cells with receptive fields (RFs) are indicated by long ticks; those without are indicated by short ticks. The cold sensation evoked is indicated by filled circles at the end of the tick to the left of the trajectory. Scale is as indicated. Each site where a cell was recorded or stimulation was carried out or both is indicated by the same number in (b) and (c). The core of Vc and the regions posterior and inferior are as labelled. (c) P1 and P2 show the site number, PF, and RF for that site. The threshold (in microamperes) is indicated below the PF diagram. Reprinted from Ohara S. and Lenz F. A. (2003) Medial lateral extent of thermal and pain sensations evoked by microstimulation in somatic sensory nuclei of human thalamus. J. Neurophysiol. 90, 2367-2377, used with permission from the American physiological society.

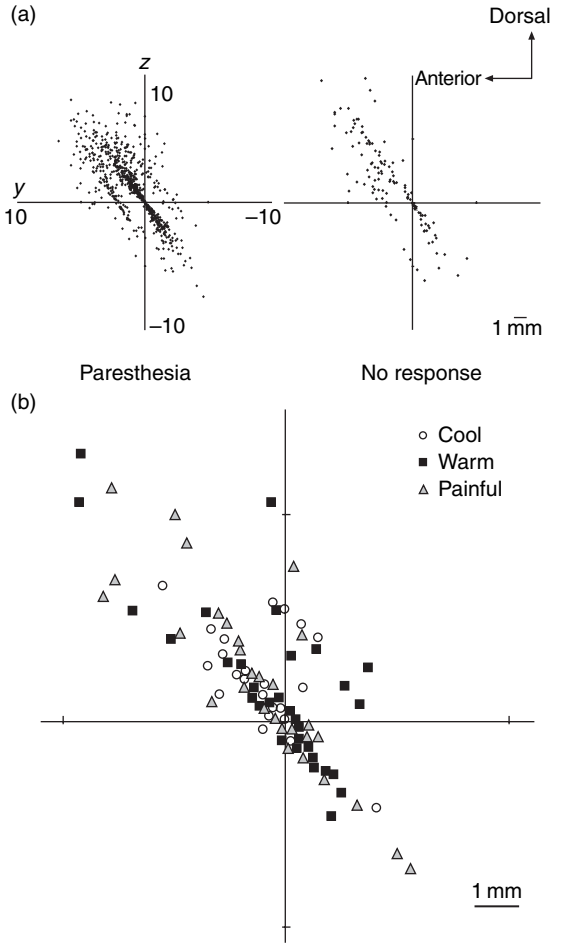

Figure 3 Locations of sites where microstimulation evoked paresthesias (a, left), no response (NR) (a, right), and thermal and pain sensations (b). Site location is shown relative to the posterior and inferior borders of the core of Vc. Note that thermal and pain sensations were evoked both in the core and posterior regions of Vc. Paresthesic sites are most dense where NR sites are least dense over the core and the posterior regions. Scale as indicated. Reprinted from Ohara S. and Lenz F. A. 2003. Medial lateral extent of thermal and pain sensations evoked by microstimulation in somatic sensory nuclei of human thalamus. J. Neurophysiol. 90, 2367-2377, used with permission from the American Physiological Society.

Warm sensations were evoked more frequently in the lateral plane (10.8%) than in the medial planes of the posterior region (3.9%) but no other significant medial lateral differences for any sensation were found in the core or posterior region or overall.

These results are in contrast to previous studies reporting a larger proportion of thermal/pain sites were evoked in the posterior and inferior regions (Lenz, F. A. *et al.*, 1993b; Davis, K. D. *et al.*, 1996). These latter studies took the anterior commissure–posterior commissure line (ACPC) as the floor of Vc, contrary to atlas and physiologic maps (Schaltenbrand, G. and Bailey, P., 1959; Lenz, F. A. *et al.*, 1988). This recent study suggests that sites where thermal or pain sensations are evoked are located both within and posterior, inferior, and medial to Vc. If the proportion of such sites is larger in posterior and inferior regions, then those sites must be very close to the borders of the core.

Patterned stimulation at sites in the region of Vc, an STT terminal region, evokes sensations consistent with one of two pathways – one binary (pain+) and the other analog (pain−/+) (Figure 3). Specifically, current was applied at five frequencies (10, 20, 38, 100, and 200 Hz) in bursts of 4, 7, 20, 50, and 100 pulses in an ascending staircase protocol, the type of protocol commonly used in studies of pain (Gracely, R. H. *et al.*, 1988; Yarnitsky, D. and Sprecher, E., 1994), including our studies (Greenspan, J. D. *et al.*, 2004). Stimulation at pain+ sites evoked a constant high level of pain over large, often cutaneous, projected fields (PFs). These sites were characterized both by descriptors, which did not change along the staircase, or by more intense stimulation-evoked pain than that evoked at the pain−/+ sites (Figure 4). These results suggest that pain+ sites participate in a binary, exteroceptive, labeled line which signals the presence of a painful external stimulus.

The thalamic stimulation thresholds for nonpainful and painful sensations are not significantly different (Lenz, F. A. *et al.*, 1993b; Ohara, S. *et al.*, 2003) suggesting that pain−/+ sites did not result from activation of the system transmitting nonpainful sensations (largely medial lemniscal) before that transmitting painful sensations (largely STT) (Willis, W. D., 1985). In addition, the equivalence of current, pulse, and frequency thresholds for pain at both types of sites predicts that the neural elements, that is, possibly WDR and NS cells, should be activated together if they were found at the same site. At such sites, analog pain+ responses would be predicted to occur because the combination of binary plus analog neural elements at a site will have analog properties, given the assumption of linearity. However, analog pain+ sites were not observed. For all these reasons, it is plausible that our observations may be the result of selective activation of two functionally distinct pathways.

Figure 2(a) demonstrates the mean firing rate minus baseline (Figure 2(b), x-axis) for the response of multiple single WDR and NS neurons to painful stimuli versus VAS score (Figure 2(b), y-axis). There

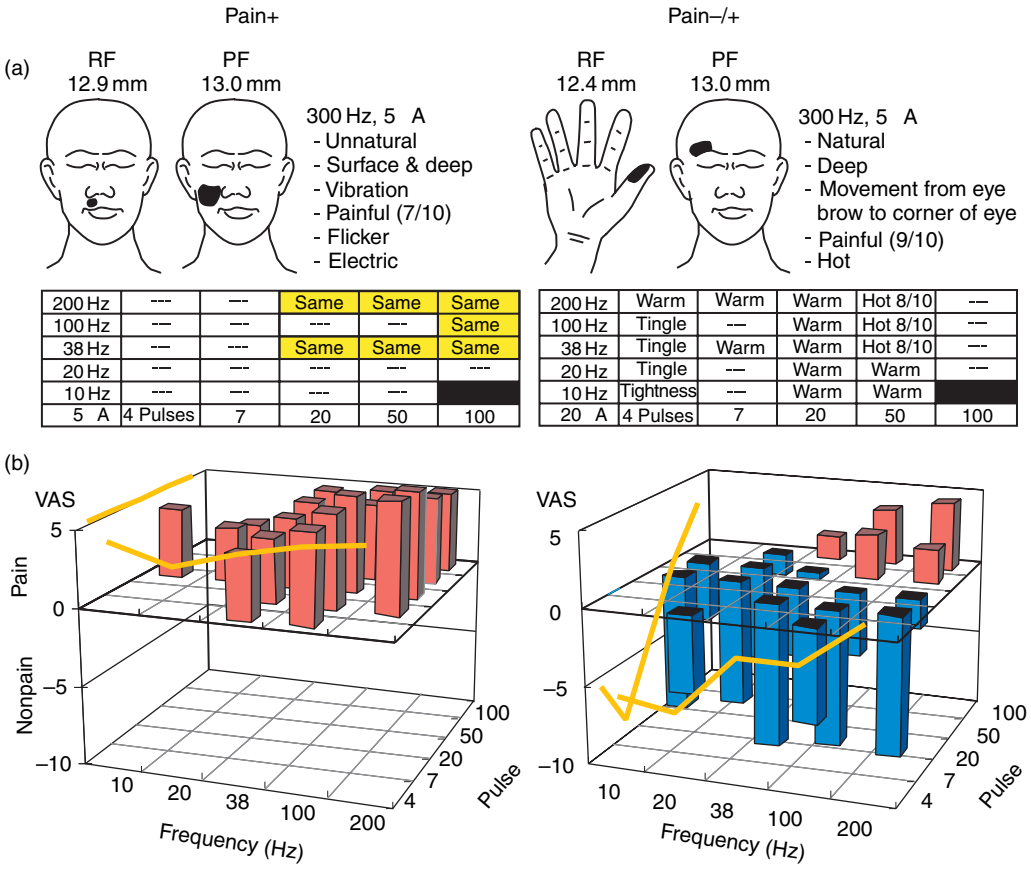

Figure 4 Pain+ and pain−/+ stimulation sites. Sensations evoked by threshold microstimulation were characterized by the PF and by descriptors from a validated questionnaire, and by a visual analog scale of intensity (VAS) (Lenz, F. A. *et al.*, 1993b; 1998a; Lenz, F. A. and Byl, N. N. 1999). (a, left) Site where stimulation at 300 Hz and 5 μA produced pain in the PF shown in the figurine and of the quality as described. Pain identical to that evoked by 300 Hz was evoked at most sites with trains ≥20 pulses and frequencies ≥200 Hz (yellow rectangle, see text). (a, right) Site where tightness was evoked in the first column at 10 Hz and then tingle at 20, 38, and 100 Hz. At 200 Hz and thereafter, warm was evoked at each step in the staircase, excepting 7 pulses – 10, 20, 100 Hz, until 50 pulses – 38 Hz. At this step and further up, the staircase painful heat was evoked. (b) Average VAS ratings across all pain+ and pain−/+ sites. Ratings were taken in response to pulse and frequency pairs ascending the staircase. The yellow lines along the outside surfaces of the 3D displays indicate the average VAS ratings across all sites by frequency and number of pulses. Reprinted from Lenz F. A., Ohara, S., Gracely, R. H., Dougherty, P. M., and Patel, S. H. 2004. Pain encoding in the human forebrain: binary and analog exteroceptive channels. J. Neurosci. 24, 6540-6544, with permission (©2004; by the Society for Neuroscience).

was a significantly steeper initial rise in VAS scores for the neurons that only responded to painful stimuli (NS neurons), than for WDR neurons. The steep initial rise of VAS with the firing rate of NS versus WDR neurons (Figure 2(b)) is consistent with the shorter dynamic range of thalamic NS cells (Apkarian, A. V. and Shi, T., 1994), and with the binary response to stimulation at pain+ sites (Figure 2(b)).

We suggest that the first pathway is characterized as a binary pain response signaling the presence/absence of painful stimuli, consistent with an alerting/alarm function (Becker, D. E. *et al.*, 1993; Zaslansky, R. *et al.*, 1995). The second pathway may be an analog route in which activity is graded with intensity of the painful stimulus, consistent with STT neurons, which encode the properties of external stimuli (Willis, W. D., 1985; Price, D. D. *et al.*, 2003). Itch was rarely evoked and never in isolation. Emotion descriptors (e.g., nauseating, cruel, suffocating) were uncommonly endorsed at either pain+ and pain−/+ sites (cf. Lenz, F. A. *et al.*, 1995). Therefore, both painful responses to stimulation were described in terms usually applied to external stimuli (exteroception) rather than to internal or emotional phenomena

(interoception). Exteroreceptive sensations can be associated with a strong affective dimension.

Pain with a strong unpleasant or affective component can be evoked by stimulation of the lateral thalamus in the region of Vc. These sensations have the character of memories of a previously experienced pain, unlike the pain sensations evoked by thalamic sensation which are not related to previous experience (see above) or a diffuse unpleasant sensation of the type evoked by stimulation of the medial thalamus (see below). In the first case, stimulation in Vcpc (Figure 5) evoked chest pain with an affective dimension in the case of a patient with coronary artery disease which had been effectively treated by balloon angioplasty (Lenz, F. A. *et al.*, 1994a).

Microstimulation at site 49 (Figure 5) evoked an unnatural, painful (visual analog scale – 4.6/10), mechanical sensation in the flank and an unnatural nonpainful electrical sensation involving the left arm and leg. At sites 51 and 53 (Figure 5) microstimulation evoked a sensation described by the patient as "heart pain," which was "like what I took nitroglycerin for" except that "it starts and stops suddenly." It was not accompanied by dyspnea, diaphoresis, or after effects. The PF involved the precordium and left side of the chest from the sternum in the midline to the anterior axillary line. Microstimulation at site 51 also evoked a sensation of nonpainful surface, tingling in the left leg, which coincided with the stimulation-associated angina.

Characteristics of the patient's stimulation-associated angina and usual angina were measured by using a questionnaire. The same descriptors for stimulation-associated angina were chosen intraoperatively during stimulation at both sites 51 and 53 (Figure 5) including: natural, deep, painful (visual analog scale – 10/10), squeezing, frightful, fatiguing, and identical to her angina. The questionnaire was administered three times over several months postoperatively to describe the patient's usual angina. The following descriptors were chosen: natural (3/3 administrations), deep (3/3), painful (3/3), squeezing (3/3), frightful (2/3), suffocating (2/3), and fatiguing (2/3). Her usual angina involved the left side of the chest, arm, and neck and was associated with a surface (3/3), nonpainful (3/3), and tingling (3/3) in the left arm and hand. This coincidence of descriptors is unlikely to occur at random ($p < 10^{-6}$, combinatorial analysis).

Similar emotional responses, including crying in response to thalamic stimulation in the same region, have been reported in the case of atypical chest pain, dysparunia, and the pain of childbirth (Davis, K. D.

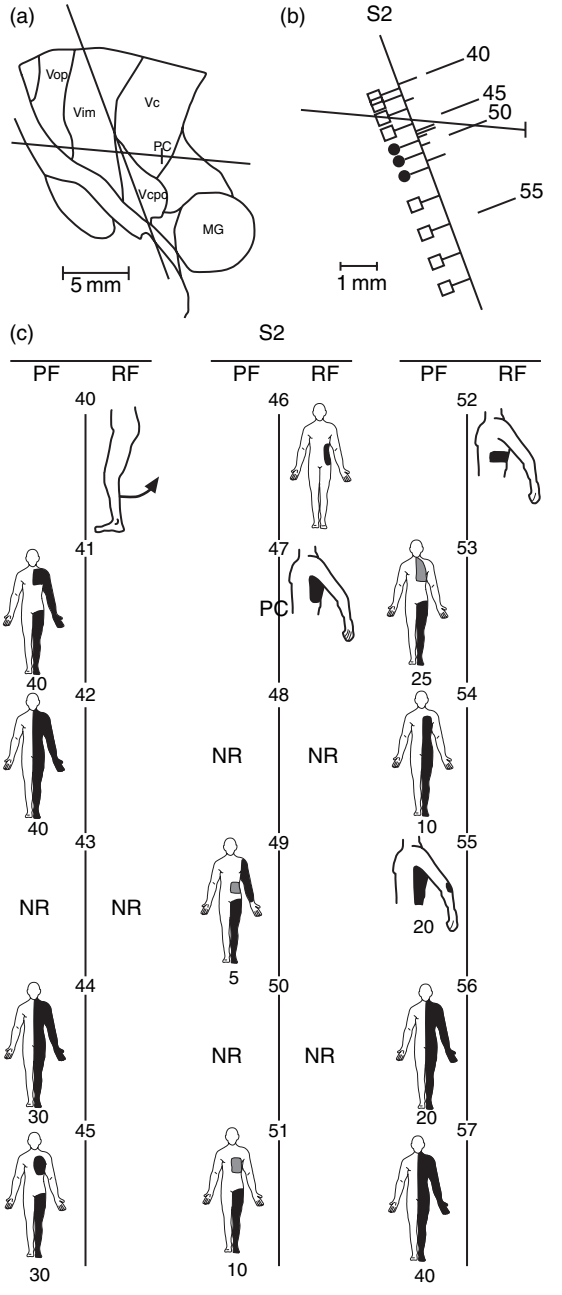

Figure 5 (a) Thalamic map of a patient with a history of angina pectoris successfully treated with coronary artery balloon angioplasty. (b) Dark circular balloons on ticks to the right of the line indicate sites (sites 49, 51, 53) where thalamic microstimulation evoked painful sensations in PFs indicated by stippling in the figurines (c). Open square balloons in (b) indicate sites where nonpainful, tingling sensations were evoked. All abbreviations and other conventions are as in the legend to Figure 1. Reproduced from Lenz F. A., Gracely, R. H., Hope, E. J., Baker, F. H., Rowland, L. H., Dougherty, P. M., and Richardson, R. T. 1994a. The sensation of angina can be evoked by stimulation of the human thalamus. Pain 59, 119-125, with permission from Elsevier.

et al., 1995; Lenz, F. A. *et al.*, 1995). Clinical criteria including a battery of cardiac tests (enzymes, EKGs, stress test) ruled out angina of cardiac origin in both these patients. Explorations in 50 patients without a history of angina found that stimulation-associated angina was not evoked at any of the 19 stimulation sites with PFs on the chest wall. PFs were located on the left chest wall at three sites and the right chest wall at 16. At one of these 19 sites an unnatural, sharp, mechanical, painful, and vibration was described in response to stimulation but emotional descriptors were not endorsed.

Preoperative pain was clearly of cardiac origin in the patient with angina (Lenz, F. A. *et al.*, 1994a), but clearly not of cardiac origin in the patient with panic disorder. The association of stimulation-associated angina and the affective dimension was not unexpected (Lenz, F. A. *et al.*, 1994a) as angina is often associated with a strong affective dimension, unlike other chest pains (Matthews, M. B., 1985; Braunwald, E., 1988; Procacci, P. and Zoppi, M., 1989; Pasternak, R. C. *et al.*, 1992). Stimulation-evoked sharp chest pain occurred without an affective dimension in a retrospective analysis of patients without prior experience of spontaneous chest pain with a strong affective dimension. Therefore, it is possible that in the case, stimulation-associated chest pain included an affective dimension as a result of conditioning by the prior experience of spontaneous chest pain with a strong affective dimension. In retrospect, the affective dimension of stimulation-associated angina might arise by similar conditioning.

5.44.4.2 Medial and Intralaminar Thalamic Nuclei

The medial and intralaminar nuclei also play a role in signaling pain sensations. Medial to Vc, the most dense STT terminal pattern is found in the intralaminar nucleus centralis lateralis (Mehler, W. R., 1962; 1969), while a much less dense termination is found in other interlaminar nuclei central medial, parafascicularis (Mehler, W. R., 1962), and the medial dorsal nucleus (Mehler, W. R., 1969). Nociceptive neurons have been identified in an area that apparently corresponds to the human central median nucleus (Ishijima, B. *et al.*, 1975; Tsubokawa, T. and Moriyasu, N., 1975; Rinaldi, P. C. *et al.*, 1991).

Milliampere-current-level stimulation at sites probably located in the parafascicular, limitans, and central medial (parvocellular part) nuclei was reported to evoke a diffuse, burning pain, or sometimes to exacerbate the patient's ongoing pain (Sano, K., 1979). This pain was evoked in projected fields as large as the whole body or hemibody. Stimulation at sites, possibly the medial dorsal and periventricular nuclei evoked a generalized unpleasant sensation, not localized to a particular body part (Sano, K., 1979). Both responses may be consistent with the STT pathway or a multisynaptic pathway traversing the reticular formation (Willis, W. D., 1985).

5.44.5 Cortex

Functional imaging studies of the response to the application of painful stimuli (Jones, A. K. *et al.*, 1991; Talbot, J. D. *et al.*, 1991; Casey, K. L. *et al.*, 1994; Craig, A. D. *et al.*, 1996; Andrew, D. *et al.*, 2001) have identified three cortical areas with metabolic activation: primary somatosensory, parasylvian, and cingulate cortex. These cortical areas all receive input arising from nociceptors as demonstrated by cortical potentials evoked by cutaneous application of a laser (laser-evoked potentials – LEP) (Ohara, S. *et al.*, 2004b), which selectively activates nociceptors (Bromm, B. *et al.*, 1984). Pain-related responses to stimulation have been identified in relation to the parasylvian cortex.

5.44.5.1 Parasylvian Cortex and Pain Memory

Parasylvian cortex receives input from the nuclei around, and subnuclei within Vc (Van Buren, J. M. and Borke, R. C., 1972) such as Vcpc, Vcpor, and putative VMpo. Parasylvian receives nociceptive input as evidenced by the presence of neurons responding to noxious stimuli (Robinson, C. J. and Burton, H., 1980; Dong, W. K. *et al.*, 1989; 1994) and of LEP generators (Lenz, F. A. *et al.*, 1998c; Vogel, H. *et al.*, 2003; Ohara, S. *et al.*, 2004b). The LEP generator is anterior to primary auditory cortex, adjacent to the S2 (secondary somatosensory cortex) generator for vibratory SEPs (somatosensory-evoked potentials) (Hamalainen, H. *et al.*, 1990; Ohara, S. *et al.*, 2004b). Source modeling suggests that the LEP generator is in the dorsal insula–parietal operculum (Figure 6) (Lenz, F. A. *et al.*, 1998b; Vogel, H. *et al.*, 2003), different from the location of the local generator for the P3 event-related potentials in the temporal base (Lenz, F. A. *et al.*, 1998b). Differences between the locations of the late component of the LEP, the P2 wave, and the P3 suggest that the LEP P2 is not a P3-

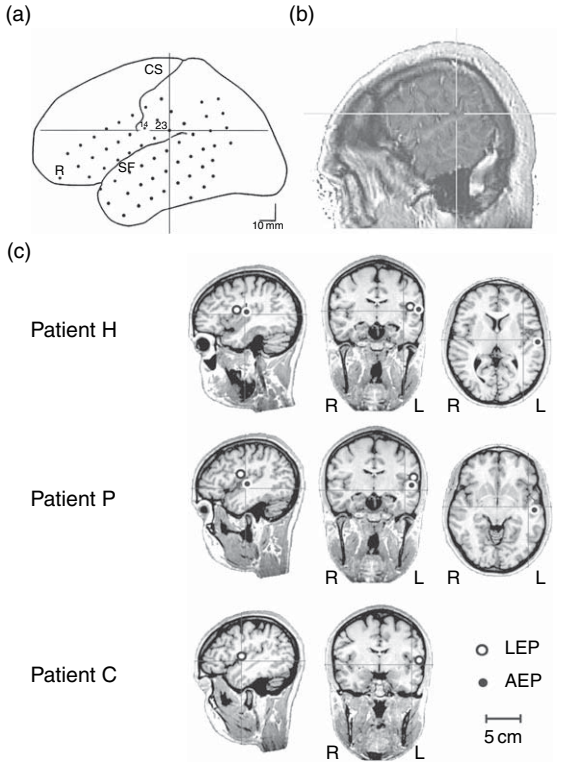

Figure 6 Verification of subdural grid electrode position in head model for dipole source analysis. Positions of all subdural grid electrodes were determined in a postoperative CT scan. These positions were entered into a spherical head model for dipole source analysis, from which they were projected back into a preoperative magnetic resonance imaging (MRI) of this patient's brain (patient H). (a) Intraoperative sketch shows the sylvian fissure with frontotemporal grid electrode 23 near the end of the fissure, and electrode 14 just posterior of the central sulcus. (b) Location of electrode 23 was projected from brain electromagnetic source analysis software (BESA) head coordinates into the preoperative MRI, showing excellent coincidence of the different coordinate systems used in this study. A similar correlation was found for electrode 14 and the central sulcus. (c) Projection of dipole source locations for LEP (○) and auditory – evoked potentials (AEP) (●). The projection was performed in Talairach space of a standard brain MRI. Left to right, panels show sagittal, coronal, and axial sections in patients H, P, and C, top to bottom. The LEP source was located above the sylvian fissure, and the AEP was located further posterior and below the fissure. The axial slice was aligned to pass through Heschl's gyrus (AEP generator) to illustrate the relative location of the source of the AEP (available only in patients H and P). Reprinted from Vogel H., Port, J. D., Lenz, F. A., Solaiyappan, M., Krauss, G., and Treede, R. D. 2003. Dipole source analysis of laser-evoked subdural potentials recorded from parasylvian cortex in humans. J. Neurophysiol. 89, 3051–3060, used with permission the American Physiological Society.

like wave, signaling the alertness evoked by painful stimuli (Zaslansky, R. *et al.*, 1995; Lenz, F. A. *et al.*, 1998b). Rather, it is likely that the LEP P2 is primarily related to the sensation of pain (Ohara, S. *et al.*, 2004a).

The pain-related function of this area is consistent with decreased pain discrimination and tolerance with lesions of the parietal operculum and insula, respectively (Greenspan, J. D. *et al.*, 1999). Studies in which LEPs were recorded through depth electrodes implanted in S2 and insula did not show a phase reversal in the parietal operculum, that is, S2 (Frot, M. *et al.*, 1999). Stimulation through electrodes placed in the posterior, superior insula produced pains described as burning, stinging, electrical, and disabling sensations (Ostrowsky, K. *et al.*, 2002). In a earlier series, stimulation of the exposed insula during awake craniotomies ($n = 5$) produced pain uncommonly but did produce nausea, tastes, somatic sensations in the epigastric area, and rising sensations in the epigastric and umbilical areas (Penfield, W. and Jasper, H. 1954). Thus there is evidence from human stimulation studies that insula, possibly the posterior–superior portion, is involved in pain-related processes.

Pain with a strong, vivid, affective dimension evoked by stimulation of the region of Vc may be related activation of its parasylvian cortical projection zone (see Section 5.44.4.1) (Locke, S. *et al.*, 1961; Mehler, W. R., 1962; Van Buren, J. M. and Borke, R. C., 1972). These vivid memories are similar to those evoked by stimulation around the lateral sulcus in patients with epilepsy (Halgren, E. *et al.*, 1978; Gloor, P. *et al.*, 1982b; Gloor, P., 1990). These memories may be related to cortical activation rather than medial temporal structures as they are not fully formed memories like those described here (Halgren, E. *et al.*, 1978; Gloor, P. *et al.*, 1982a). Furthermore, fully formed memories can be evoked after removal of mesial temporal structures (Moriarity, J. L. *et al.*, 2001). Therefore, pain with a strong affective dimension in response to thalamic stimulation results might be related to the activation of limbic and associated cortical structures (Lenz, F. A. *et al.*, 1995). The role of the medial temporal lobe might be transiently involved in the formation of these memories, before being located in cortex, independent of medial temporal lobe structures (Mishkin, M., 1979; Friedman, D. P. *et al.*, 1986; Zola-Morgan, S. and Squire, L. R., 1990).

Painful stimuli sometimes lead to long-term changes in pain processing, as well as to signaling

the presence of the stimulus. This appears to be the situation in the case of stimulation sites in and posterior to Vc, where stimulation can evoke complex, fully formed, pain in patients with angina or atypical chest pain. These memories seem to be due to long term changes in forebrain function, that is, conditioning, since memories of this type have not been reported in response to STT stimulation.

S2 and insular cortical areas involved in pain processing also satisfy criteria for areas involved in memory through corticolimbic connections (Mishkin, M., 1979). In monkeys, a nociceptive submodality selective area has been found within S2 (Dong, W. K. *et al*., 1994; Willis, W. D., Jr. *et al.,* 2001). S2 cortex projects to insular areas that project to amygdala (Friedman, D. P. *et al*., 1986). S2 and insular cortex have bilateral primary noxious sensory input (Chatrian, G. E. *et al*., 1975), and cells in these areas responding to noxious stimuli have bilateral representation (Dong, W. K. *et al*., 1994) and project to the medial temporal lobe (Chatrian, G. E. *et al*., 1975; Dong, W. K. *et al*., 1989). Parasylvian cortical areas receive input from nociceptive subnuclei within Vc, and from nuclei nearby (see Lateral Thalamic Nuclei) and so may be involved in memory for pain (Burton, H., 1986). This proposal is consistent with Mishkin's hypothesis of somatic sensory memory mediated through corticolimbic connections (Mishkin, M., 1979).

5.44.6 Conclusions

These stimulation results are consistent with those of functional imaging studies that have identified brain regions activated in a binary fashion by the application of a very specific, painful stimulus, while further increases in stimulus intensity do not produce increased activation. These brain regions may also mediate the long-term relationship of some intense pains to the strong affective dimension, which accompanies them. This relationship may also explain the affective dimension of chronic pain, which results from an intensely painful experience. These complex experiences of pain are not evoked by stimulation of the STT, again suggesting that these memories of pain involve conditioning of forebrain structures, rather than simple activation by a painful stimulus.

ACC anterior cingulate cortex (n.b.: some authors use this as a summary term for ACC and MCC)
CBP Chronic back pain
CRPS Complex regional pain syndrome
EEG Electro-encephalography
fMRI Functional magnetic resonance imaging
IBS Irritable bowel syndrome
IC Insular cortex
MCC mid-cingulate cortex (n.b.: some authors call this region the posterior part of ACC)
MEG Magneto-encephalography
MRS Magnetic resonance spectroscopy
OIC Operculo-insular cortex, consisting of insular cortex plus the frontal, parietal and temporal operculum.
PAG Periaqueductal grey
PET Positron emission tomography
PFC prefrontal cortex
PHN Postherpetic neuralgia
SI Primary somatosensory cortex
SII Secondary soamtosensory cortex
SCI Spinal cord injury
SPECT Single photon emission computed tomography
Th Thalamus

5.45.1 Introduction

Conscious perception of external stimuli requires encoding by sensory organs, processing within the respective sensory system, and activation of the appropriate sensory cortical areas. Based on a small case series of infra- and supratentorial brain lesions, Head H. and Holmes G. (1911) postulated that the sensation of pain is an exception to this rule and that its conscious perception occurs in the essential organ of the thalamus. In spite of evidence to the contrary from clinical reports (Marshall, J., 1951; Biemond, A., 1956), evoked potentials in humans (Spreng, M. and Ichioka, M., 1964; Duclaux, R. *et al.*, 1974; Carmon, A. *et al.*, 1976; Chen, A. C. N. *et al.*, 1979; Bromm, B. and Treede, R. D., 1984), single unit recordings in animals (Lamour, Y. *et al.*, 1982; Kenshalo, D. R. and Isensee, O., 1983), neuroanatomical tracing (Gingold, S. I. *et al.*, 1991), and some early PET studies (Buchsbaum, M. S. *et al.*, 1984), it was maintained for a long time that the cortical representation of pain is a *quantité négligable*.

This situation changed, when the modern neuroimaging techniques of positron emission tomography (PET) and later functional magnetic resonance imaging (fMRI) demonstrated systematic metabolic and perfusion changes in a large number of cortical areas following painful stimuli (Talbot, J. D. *et al.*, 1991; Jones, A. K. P. *et al.*, 1991a; Apkarian, A. V. *et al.*, 1992; Davis, K. D. *et al.*, 1995). These findings were supported by invasive and noninvasive electrophysiological studies in humans, using magnetoencephalography (MEG), electroencephalography (EEG), subdural recordings directly from the surface of the brain, and depth recordings during stereotactic procedures (for a systematic review see Apkarian, A. V. *et al.*, 2005).

Meanwhile it has been recognized that painful stimuli activate a vast network of cortical areas, including the primary and secondary somatosensory cortex (SI, SII), the insula, posterior parietal cortex, anterior and mid-cingulate cortex, and parts of the prefrontal cortex (PFC; Figure 1). These areas are involved in the generation of painful percepts as well as in the descending control of pain (for review see Kenshalo, D. R. and Willis, W. D., 1991; Treede, R. D. *et al.*, 1999; Price, D. D., 2000; Apkarian, A. V. *et al.*, 2005). Most of these areas are also involved in other sensory, emotional, cognitive, motor or autonomic functions. Hence, the nociceptive system converges with other systems for the generation of the conscious percept of pain. In that sense, the nociceptive system is not different from the visual system, for example. But it is still an open question, to what extent any cortical regions can be considered as nociceptive specific.

In this chapter we will briefly review the methods used to assess nociceptive processing in the human brain, present connectivity and functional properties of each of the principal cortical regions of the nociceptive system, and summarize the roles of the cerebral cortex in various aspects of pain perception and pain modulation.

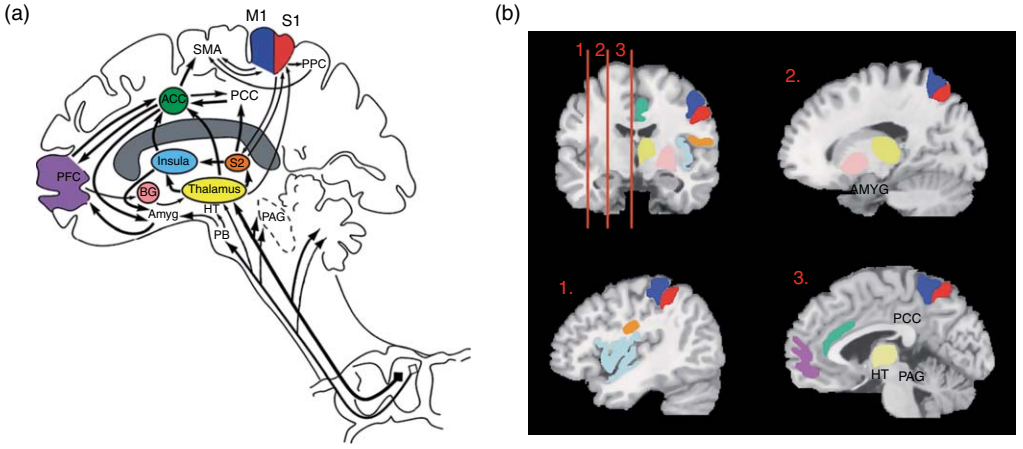

Figure 1 Cortical regions involved in pain perception, their interconnectivity and ascending pathways. Locations of brain regions involved in pain perception are color coded in a schematic drawing and in an example magnetic resonance image (MRI). (a) Schematic diagram shows the regions, their interconnectivity, and afferent pathways. (b) The areas corresponding to those shown in the schematic are shown in an anatomical MRI, on a coronal slice and three sagittal slices as indicated on the coronal slice: primary and secondary somatosensory cortices (S1, S2, red and orange), anterior and mid-cingulate cortex (ACC, green), insula (blue), thalamus (yellow), prefrontal cortex (PFC, purple), primary and supplementary motor cortex (M1 and SMA), posterior parietal cortex (PPC), posterior cingulate cortex (PCC), basal ganglia (BG, pink), hypothalamus (HT), amygdala (AMYG), parabrachial nuclei (PB), and periaqueductal gray (PAG). Reproduced from Apkarian, A. V., Bushnell, C., Treede, R. D., and Zubieta, J. K. 2005. Human brain mechanisms of pain perception and regulation in health and disease. Eur. J. Pain 9, 463–484.

5.45.2 Methods to Study Nociceptive Processing in the Human Cerebral Cortex

Table 1 summarizes properties of the different brain imaging techniques that have been used to define the nociceptive network in the human brain. The most direct approach to learn about the functions of cortical neurons is direct intracellular or extracellular recording of their electrical activity during sensory stimulation and in different contexts. This technique is mostly restricted to animal studies (Kenshalo, D. R. and Isensee, O., 1983; Dong, W. K. *et al.*, 1994) and has rarely been possible in humans (Hutchison, W. D. *et al.*, 1999). Field potentials within the brain invert their polarity, when an electrode track passes through or close to their generator source. This technique has been used in the course of presurgical epilepsy diagnostics (Frot, M. and Mauguière, F., 1999), but since the electrode tracks are related to the clinical indications, only few parts of the brain have been sampled that way. Presurgical epilepsy diagnostics using subdural electrode grids samples a much larger part of the brain surface, and dipole source analysis can be used to estimate the depths of the generators below the grids (Vogel, H. *et al.*, 2003). All of these invasive recordings in the human brain need to be interpreted with caution, because the cortical pathology that provided the indication for the procedure (e.g., epilepsy, tumors) may have altered nociceptive signal processing.

EEG and MEG are noninvasive techniques for the direct assessment of electrical activity in the brain. Mathematical algorithms are available to estimate the location of the generators within the brain from the signals recorded at the surface of the head with an accuracy of about 10 mm (Scherg, M., 1992; Pascual-Marqui, R. D. *et al.*, 1994; Hari, R. and Forss, N., 1999). EEG and MEG techniques provide accurate timing information. As a result, both methods have been used mainly to identify the arrival of information to various cortical regions (stimulus-evoked potentials). Spontaneous fluctuations in EEG and MEG would provide a view of the interactions between cortical areas. However, the application of the latter to painful states has remained minimal (Chen, A. C. N., 1993; Ohara, S. *et al.*, 2006). MEG detects brain magnetic activity, a signal that is proportional and orthogonal to the local electrical activity. Depending on the orientation of a local generator source and the gyral geometry of the brain region, evoked potentials in different brain areas may be better detected by MEG or EEG. The main weakness of EEG and MEG methods is their limited spatial resolution (on the order of 1 cm for both methods).

PET, single photon emission-computed tomography (SPECT), and fMRI measure brain activity

Table 1 Brain mapping techniques, their properties, and application in pain studies

Method	*Energy source*	*Spatial resolution (mm)*	*Temporal resolution (s)*	*Constraints*	*Output measured*	*Application in pain studies*
EEG/MEG	Intrinsic electricity	10	0.001	Lack of unique localization	Electrophysiology of brain events	Increasing in use, mainly for detecting temporal sequences
fMRI	Radio waves, magnetic fields	4–5	4–10	Immobilization, loud, cooperation	Relative cerebral blood flow	Most used, mainly for localizing brain activity
MRS	Radio waves, magnetic fields	10	10–100	Immobilization, loud	Relative chemical concentrations	Recently used, for detecting long term changes in brain chemistry
Nuclear (PET/ SPECT)	Radiation	5–10	60–1000	Radiation limits, immobilization	Physiology, neurochemistry, absolute values	Decreasing in use, becoming limited to neurochemistry
Brain imaging techniques available but rarely or not yet used in pain studies						
Single or multiunit electrophysiology	Intrinsic electricity	0.01–1	0.001	Invasive, direct access to brain	Electrophysiology	
Near infrared spectroscopy and imaging	Infrared light	0.05	0.05	Immobilization, surface > depth, limited field of view	Relative cerebral blood flow	
Transcranial magnetic/ electric stimulation	Magnetic/ electric fields	10	0.01	Risk of seizures, immobilization, loud	Electrophysiology, conduction times	
Structural MRI	Radio waves, magnetic fields	1	N/A	Immobilization, loud	Structure, vasculature, white matter	
Postmortem	N/A	0.001	N/A	Postmortem	Microarchitecture, chemoarchitecture	

EEG, electroencephalography; MEG, magnetoencephalography; fMRI, functional magnetic resonance imaging; MRS, magnetic resonance spectroscopy; PET, positron emission tomography; SPECT, single photon emission-computed tomography; N/A, not applicable.

indirectly by imaging changes in blood flow, blood oxygenation, or local metabolic changes (Peyron, R. *et al.*, 2000; Davis, K. D., 2003). All three methods can provide similar spatial resolution, although PET and fMRI methodologies are now far more advanced than SPECT. The statistical models and experimental designs available for PET and fMRI are robust and very rich. Therefore, these two techniques are currently most extensively used for detecting brain circuitry underlying many cognitive states, including pain. The temporal resolution of PET and SPECT is in the order of tens of seconds, while for fMRI it is shorter. PET and SPECT provide the additional opportunity for examining *in vivo* biochemistry and pharmacology by imaging the distributions of specific neurotransmitters or receptors. Recent MRI methods, like magnetic resonance spectroscopy (MRS), have also provided the ability to examine brain biochemistry. This approach is developing rapidly and has the potential to become a major method in the near future for studying brain chemistry. In addition, voxel based morphometry allows to image structural changes related to disease states (May, A. *et al.*, 1999).

5.45.3 Cortical Regions that are Part of the Nociceptive System

5.45.3.1 The Primary Somatosensory Cortex

The primary somatosensory cortex (SI) is located in the anterior part of the parietal lobe, where it constitutes the postcentral gyrus. It consists of Brodmann areas 1, 2, 3a, and 3b (Figure 2(a)). Areas 3b and 1 receive cutaneous tactile input, areas 3a and 2 proprioceptive input.

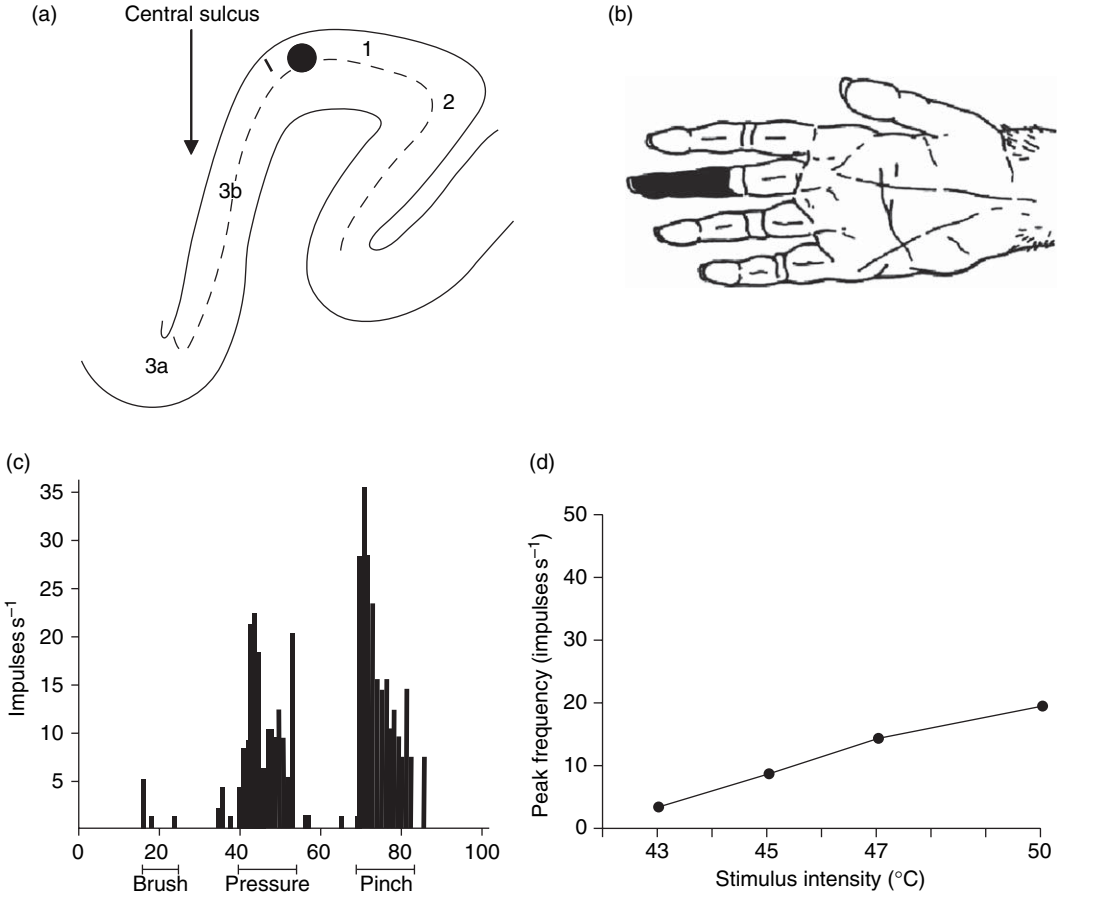

Figure 2 Nociceptive specific neuron in the primary somatosensory cortex (SI). (a) Left: SI consists of Brodmann areas 1, 2, 3a, and 3b in the postcentral gyrus. Black dot: location of the recorded neuron. (b) The small receptive field is consistent with a role in spatial discrimination. (c) Stimulus response function to painful mechanical stimuli. (d) Stimulus response function to painful heat stimuli. Modified from Kenshalo, D. R., Iwata, K., Sholas, M., and Thomas, D. A. 2000. Response properties and organization of nociceptive neurons in area 1 of monkey primary somatosensory cortex. J. Neurophysiol. 84, 719–729.

Nociceptive input to monkey SI was demonstrated anatomically. SI receives direct spinothalamocortical input from the ventrobasal nuclei, in particular the ventro-posterolateral (VPL) nucleus (Gingold, S. I. *et al.*, 1991). Nociceptive neurons in SI are found in clusters, raising the possibility that SI may contain nociceptive specific columns (Lamour, Y. *et al.*, 1983). Since evidence for nociceptive neurons in the most superficial cortical layers is lacking, this hypothesis has not yet been confirmed. Nociceptive neurons are rare in monkey SI and have mainly been found in area 1 (Kenshalo, D. R. *et al.*, 2000), whereas optical imaging techniques have also suggested nociceptive input to area 3a (Tommerdahl, M. *et al.*, 1996). Thus, nociceptive signal processing within SI may be spatially distinct from tactile signal processing that is primarily directed to area 3b. There is also some EEG and MEG evidence in humans that nociceptive areas may be situated more medially within SI than tactile areas with the same receptive fields, suggesting that nociceptive and tactile signal processing may occur in different subareas of SI (Ploner, M. *et al.* 2000; Schlereth, T. *et al.*, 2003). Nociceptive input to human SI has been confirmed by subdural recordings (Kanda, M. *et al.*, 2000; Ohara, S. *et al.*, 2004). About 75% of the PET and fMRI studies reported activation of SI (Bushnell, M. C. *et al.*, 1999; Apkarian, A. V. *et al.*, 2005).

Nociceptive neurons in SI have small receptive fields (Figure 2(b)) that are somatotopically arranged, and hence are ideally suited to code for the location of nociceptive stimuli (Kenshalo, D. R. and Isensee, O., 1983). Somatotopy of nociceptive processing in the human SI has been confirmed by EEG and PET studies (Tarkka, I. M. and Treede, R. D., 1993; Andersson, J. L. R. *et al.*, 1997). Action potential discharges of nociceptive SI neurons in monkey are modulated by the intensity of both mechanical and heat stimuli (Figures 2(c) and 2(d)) and their discharges correlate with detection speed (Kenshalo, D. R. *et al.*, 1988). These findings suggest that nociceptive SI neurons are involved in the coding of pain intensity. This conclusion has been confirmed by a PET study of hypnotic modulation of perceived pain intensity that also modulated perfusion of SI (Hofbauer, R. K. *et al.*, 2001) and by correlation analysis (Timmermann, L. *et al.*, 2001).

5.45.3.2 Parasylvian Cortex: the Operculo-Insular Region

The parasylvian cortex has a complicated macroscopic structure and only some of its cytoarchitectonic areas have been charted in detail (Eickhoff, S. B. *et al.*, 2006). In lateral views of the brain, the Sylvian fissure runs above the temporal lobe and separates it from the parietal and frontal lobes above the fissure. Hidden deep inside the Sylvian fissure lies a further lobe of the brain: the insula (Figure 3(a)). The insula is covered by the

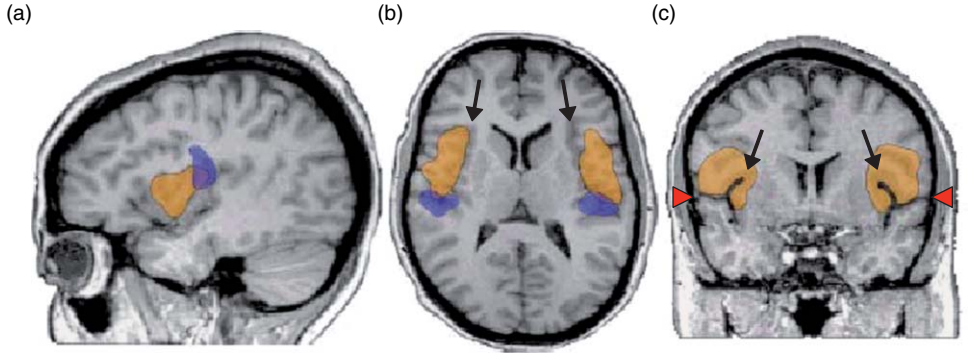

Figure 3 Nociceptive regions in parasylvian cortex. (a) Sagittal section shows the insula as a triangular region deep inside the Sylvian fissure. (b) Transaxial section illustrates the secondary somatosensory cortex (SII) as identified by tactile stimuli (blue) and regions responsive to nociceptive stimulation (orange) that extend further rostrally and medially. (c) Coronal section shows that the temporal operculum covers the insula below the Sylvian fissure, and frontal and parietal opercula cover the insula above the fissure. Frontal and parietal opercula consist of an outer part on the convexity of the brain, a horizontal part above the Sylvian Fissure, and an inner vertical part facing the insula across its circular sulcus. Arrowheads: Sylvian fissure (lateral sulcus). Arrows: circular sulcus of the insula. Modified from Treede, R. D., Baumgärtner, U., and Lenz, F. A. 2007. Nociceptive Processing in the Secondary Somatosensory Cortex. In: Encyclopedia of Pain (*eds*. R. F. Schmidt and W. D. Willis), pp. 1376–1379. Springer.

temporal, parietal and frontal opercula. Coronal sections reveal that the parasylvian cortex consists of the insula itself, the inner vertical surface of the opercula, the horizontal banks of the Sylvian fissure, and most laterally the outer surface of the convexity of the brain (Figure 3(c)).

The majority of human imaging studies showed consistent activation of the parasylvian cortex during painful stimulation, and this activation overlapped only partly with that by tactile stimuli (Treede, R. D. *et al.*, 2007). Lesions in parasylvian cortex cause deficits in pain perception (Greenspan, J. D. *et al.*, 1999), and intracortical electrical stimulation of this region is painful (Ostrowsky, K. *et al.*, 2002). Thus, this region is a good candidate to contain some nociceptive specific cortical areas, if they exist.

About 75% of the PET and fMRI studies reported activation of the SII region, and 94% found activation of the insula (Treede, R. D. *et al.*, 2000; Apkarian, A. V. *et al.*, 2005). But due to the curvature and oblique course of the Sylvian fissure (Özcan, M. *et al.*, 2005), activated areas are often misallocated, even across major sulci. Whereas the operculo-insular cortex in the parasylvian region has been recognized as one of the most important nociceptive cortical areas, its precise anatomical and functional organization has yet to be determined. In particular it is not yet known, whether insula and operculum subserve distinct functions or form one uniform area.

5.45.3.2.1 The secondary somatosensory cortex (SII)

The secondary somatosensory cortex is located in the superior bank of the Sylvian fissure, where it makes up a major part of the parietal operculum (Figures 1(b), 3(b), and 3(c)). Nociceptive input to monkey SII was demonstrated anatomically. SII receives direct spino-thalamo-cortical input from the ventrobasal nuclei, in particular the ventro-postero-inferior nucleus VPI (Stevens, R. T. *et al.*, 1993). Nociceptive input to human SII has been confirmed by subdural recordings (Lenz, F. A. *et al.*, 1998a).

Single neuron recordings in SII have largely focused on the tactile representation (Robinson, C. J. and Burton, H. 1980; Fitzgerald, P. J. *et al.*, 2006). The SII region contains multiple somatotopic representations of the body, suggesting the existence of several subregions (Disbrow, E. *et al.*, 2000, Fitzgerald, P. J. *et al.*, 2004). Although most neurons in SII have contralateral receptive fields, this is the first part of the somatosensory system with a sizable proportion of bilateral receptive fields. Hence, most imaging and electrophysiological studies in humans have shown a bilateral response to unilateral stimulation, with a contralateral preponderance. Functionally, SII is considered to play a role in tactile object recognition and memory (Seitz, R. J. *et al.*, 1991).

Evoked potential recordings in humans following brief laser heat stimuli showed that SII was activated simultaneously with or even earlier than SI (Ploner, M. *et al.*, 1999; Schlereth, T. *et al.*, 2003). Combined anterograde and retrograde tracer studies in monkey (Apkarian, A. V. and Shi, T., 1994) support the concept that nociceptive input reaches SII more directly than tactile input. Hence, SII has been supposed to be important for the recognition of painful stimuli as such.

In contrast to the abundance of evidence for nociceptive activation of the SII region from human studies, there are few single neuron recordings in this area showing specific nociceptive responses (Treede, R. D. *et al.*, 2000). In monkey, some convergence with visual input encoding the approach of a sharp object to the face has raised the possibility of a representation of threat. These neurons, however, were not in SII proper but in area 7b which is adjacent to SII in monkey but not in humans (Dong, W. K. *et al.*, 1994). These neurons are now considered to be part of the posterior parietal cortex (see below). Since neurons in all studies on SII were searched using mechanical skin stimulation, it is possible that these studies missed nociceptive specific neurons, because many primary nociceptive afferents are mechanically insensitive (Treede, R. D. *et al.*, 1998). Thus, an intriguing possibility is that tactile and nociceptive inputs are represented in different areas within the SII region.

5.45.3.2.2 The frontal operculum

Dipole source analysis of laser-evoked potentials (LEPs) in healthy volunteers, and subdural and depth recordings in patients undergoing epilepsy surgery have identified an area in the inner vertical surface of the frontal operculum (Figure 4(a)) that was activated by painful heat stimuli with a shorter latency (about 150 ms) than any other cortical area (Tarkka, I. M. and Treede, R. D., 1993; Valeriani, M. *et al.*, 1996; Ploner, M. *et al.*, 1999; Frot, M. and Mauguière, F., 2003; Schlereth, T. *et al.*, 2003; Vogel, H. *et al.*, 2003). This area anterior of the tactile SII area has a different somatotopic orientation (face: anterior, foot: posterior) than SII itself (face: lateral, foot: medial; Vogel, H. *et al.*, 2003). The thalamic source of nociceptive input to this region is not yet

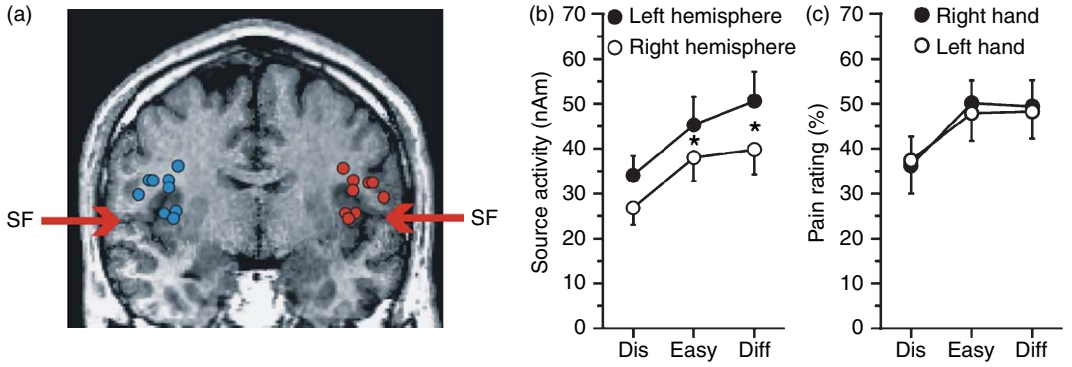

Figure 4 Nociceptive input to the frontal operculum. (a) Projection of dipole source locations for the first component of laser-evoked potentials (LEPs) onto a coronal magnetic resonance image slice at Talairach y = −6 mm. The distribution around the roof of the circular insular sulcus, ranging from the inner vertical face of the frontal operculum to the adjacent dorsal insula matches the projection area of the nociceptive thalamic nucleus VMpo. (b) Task effects and interhemispheric differences. (c) The hemispheric asymmetry of opercular activation (left hemisphere > right hemisphere) was not reflected or caused by different visual analog score pain ratings between both hands. Dis, distraction task; Easy, easy spatial and intensity discrimination tasks; diff, difficult discrimination tasks. ANOVA:* $P < 0.05$. Modified from Schlereth, T., Baumgärtner, U., Magerl, W., Stoeter, P., and Treede, R. D. 2003. Left-hemisphere dominance in early nociceptive processing in the human parasylvian cortex. Neuroimage 20, 441–454.

clear: it may be VPI like for the posteriorly adjacent SII, or it may be VMpo like for the medially adjacent dorsal insula. Somatotopy in the frontal operculum would be consistent with that of a VMpo projection target (Craig, A. D., 1995). Nociceptive input to the frontal operculum in humans has been confirmed by subdural and depth recordings (Lenz, F. A. *et al.*, 1998a; Frot, M. *et al.*, 1999). Responses in this area are modulated during spatial and intensity discrimination tasks and show a left-hemisphere dominance (Figures 4(b) and 4(c)).

5.45.3.2.3 The insula

The insula is located deep inside the Sylvian fissure, where it can be visualized as a triangular shape in sagittal sections (Figure 3(a)). It often contains two long sulci in its posterior part and three short sulci rostrally. Several functional subdivisions of the insula have been suggested (Dieterich, M. *et al.*, 2003; Schweinhardt, P. *et al.*, 2006), but there is no consensus yet. Parts of the insula subserve varied functions in the somatosensory, vestibular, gustatory and autonomic nervous system, which led to the suggestion that this region serves for a central representation of the internal state of the body (Craig, A. D., 2002). This concept is consistent with the interoceptive aspects of nociception.

Another source of nociceptive input into the parasylvian cortex is the posterior inferior part of the ventrobasal nucleus (Lenz, F. A. *et al.*, 1993), a region designated as VMpo by some authors (Craig, A. D. *et al.*, 1994). VMpo projects to the dorsal insula and the adjacent frontal operculum. Nociceptive input to the insula in humans has been confirmed by depth recordings (Frot, M. *et al.*, 2003). The somatotopic representation of pain in the dorsal insula in monkey (face: anterior, foot: posterior) is orthogonal to that in SII (face: lateral, foot: medial; Baumgärtner, U. *et al.*, 2006b). Direct electrical stimulation of the insula is painful with a strong affective component (Ostrowsky, K. *et al.*, 2002).

5.45.3.3 The Posterior Parietal Cortex

The posterior parietal cortex is located adjacent and posterior to SI. It comprises Brodmann areas 5 and 7 (Figure 5(c)). Nociceptive input to this region is suggested by studies in monkey that reported short-latency responses to nociceptive stimuli in area 7b; the same neurons also responded to visual stimuli of sharp objects directed at their receptive field (Dong, W. K. *et al.*, 1994). In the tactile system, this region is part of a dorsally directed stream involved in stimulus location, convergence with visual information and the generation of spatial information for motor control. Nociceptive input to this region in humans has not yet been explored with subdural recordings, but there is some evidence from EEG

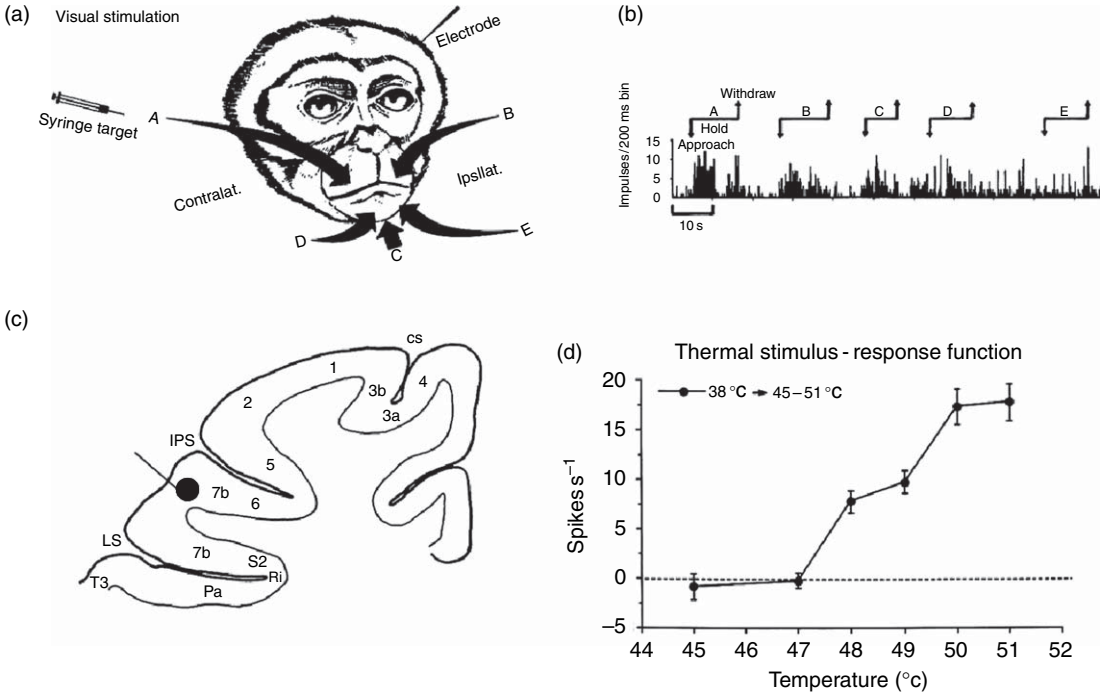

Figure 5 Nociceptive neuron in posterior parietal cortex (Area 7b threat neuron). (a) Bilateral receptive field in the orofacial region; seeing a syringe approach the receptive field was also an adequate stimulus. (b) Responses to the stimuli shown in (a). (c) Location of the recorded neuron on a coronal section that passes through both the central sulcus (CS) and the Sylvian fissure (LS: lateral sulcus). (d) Stimulus response function to painful heat stimuli. IPS, Intraparietal sulcus. Modified from Dong, W. K., Chudler, E. H., Sugiyama, K., Roberts, V. J., and Hayashi, T. 1994. Somatosensory, multisensory, and task-related neurons in cortical area 7b (PF) of unanesthetized monkeys. J. Neurophysiol. 72, 542–564.

and MEG studies in humans that nociceptive stimuli activate parietal lobe posterior of SI (Schlereth, T. *et al.*, 2003; Forss, N. *et al.*, 2005). Few fMRI studies have assessed this region (Kulkarni, B. *et al.*, 2005; Schmahl, C. *et al.*, 2006).

5.45.3.4 The Cingulate Cortex

The cingulate cortex is located above the corpus callosum and around its anterior knee (Figure 6). The anterior cingulate cortex (ACC) comprises Brodmann areas 24 and 32, whereas the posterior cingulate cortex (PCC) contains areas 23 and 31 (Vogt, B. A. *et al.*, 1995). ACC receives nociceptive thalamocortical input from the mediodorsal (MD) and parafascicular (Pf) nuclei (Vogt, B. A. *et al.*, 1979). ACC has been further subdivided into mid-cingulate cortex, which is associated with response selection and motor efferent functions, and ACC proper that is related to emotion and autonomic efferent functions (Vogt, B. A., 2005). Nociceptive input to human cingulate cortex has been confirmed by subdural recordings and by intracortical recordings (Lenz, F. A. *et al.*, 1998b; Hutchison, W. D. *et al.*, 1999). About 87% of the PET and fMRI studies reported activation of the cingulate cortex (Apkarian, A. V. *et al.*, 2005), but no region of the cingulate cortex is considered to be nociceptive specific (Vogt, B. A., 2005).

Nociceptive neurons in ACC have large or even whole-body receptive fields (Figure 7, Sikes, R. W. and Vogt, B. A., 1992; Yamamura, H. *et al.*, 1996). For this reason it is unlikely that they contribute to the sensory dimension of pain. Monkey ACC neurons activate during pain avoidance behavior, reflecting anticipation, and response selection (Koyama, T. *et al.*, 1998; 2001). The cingulate cortex is supposed to participate in the affective-motivational dimension of pain. This conclusion has been confirmed by a PET study of hypnotic modulation of perceived pain affect that also modulated perfusion of ACC (Hofbauer, R. K. *et al.*, 2001) and by correlation analysis (Tölle, T. R. *et al.*, 1999).

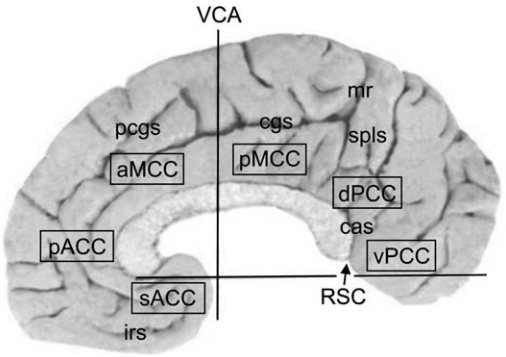

Figure 6 Distribution of cingulate cortex regions and subregions. Region borders are marked with arrows. Cross-hair shows vertical plane at the anterior commissure (VCA) and the anterior–posterior commissural line. A functional overview, derived from the analysis of a large volume of literature illustrates general regional function. aMCC, anterior mid-cingulate cortex; cas, callosal sulcus; cgs, cingulate sulcus; dPCC, dorsal posterior cingulate cortex; irs, inferior rostral sulcus; mr, marginal ramus of cgs; pACC, pregenual anterior cingulate cortex; pcgs, paracingulate sulcus; pMCC, posterior mid-cingulate cortex; RSC, retrosplenial cortex; sACC, subgenual anterior cingulate cortex; spls, splenial sulci; vPCC, ventral posterior cingulate cortex. Reproduced from Vogt, B. A. 2005. Pain and emotion interactions in subregions of the cingulate gyrus. Nat. Rev. Neurosci. 6, 533–544.

5.45.3.5 The Prefrontal Cortex

The PFC (including Brodmann areas 9, 10, 46) comprises the major part of the frontal lobe and is located anterior of the motor cortical areas. There is no evidence that it would receive a direct nociceptive thalamo-cortical input, but the PFC receives cortico-cortical input from the cingulate gyrus that may convey nociceptive information. About 55% of the PET and fMRI studies reported activation of the PRC in healthy subjects, and 81% of the studies in chronic pain patients (Apkarian, A. V. *et al.*, 2005). The PRC is assumed to participate in the cognitive-evaluative dimension of pain and in endogenous pain control (Lorenz, J. *et al.*, 2003; Schmahl, C. *et al.*, 2006).

5.45.4 Functional Roles of Cortical Nociceptive Signal Processing

Pain perception has been conceived to consist of sensory-discriminative, affective-motivational and cognitive-evaluative dimensions (Melzack, R. and Casey, K. L. 1968). The sensory-discriminative dimension includes intensity discrimination, pain qualities, stimulus localization and timing discrimination; this dimension is traditionally thought to involve lateral thalamic nuclei and the somatosensory cortices SI and SII. The affective-motivational dimension includes perception of the negative hedonic quality of pain, autonomic nervous system manifestations of emotions, and motivated behavioral responses; this dimension is traditionally thought to involve medial thalamic nuclei and the limbic cortices ACC and MCC. The insula has an intermediate position in that concept, receiving input from lateral thalamus but projecting into the limbic system. The cognitive-evaluative dimension includes interaction with previous experience, cognitive influence on perceived pain intensity and an overall evaluation of its salience; this dimension is traditionally thought to involve the PRC. Numerous neuroimaging studies have assessed various experimental paradigms derived from several psychological concepts that do not easily fit into the traditional three dimensions of pain. Therefore, we here report imaging evidence for involvement of cortical areas in specific functions instead of the dimensions of pain.

5.45.4.1 Location and Quality of Phasic Pain

Neuroimaging studies have examined brain regions activated by many types of painful stimulation, including noxious heat and cold, muscle stimulation using electric shock or hypertonic saline, topical and intradermal capsaicin, colonic distention, rectal distension, gastric distension, esophageal distension, ischemia, cutaneous electric shock, ascorbic acid, laser heat, as well as an illusion of pain evoked by combinations of innocuous temperatures (Apkarian, A. V. *et al.*, 2005; Bushnell, M. C. and Apkarian, A. V., 2005). Despite the differences in sensation, emotion and behavioral responses provoked by these different types of pain, individuals can easily identify each as being painful. Thus, there appears to be a common construct of pain with an underlying network of brain activity in the areas described above. Nevertheless, despite the similarities in pain experiences and similarities in neural activation patterns, each pain experience is unique. Subjects can usually differentiate noxious heat from noxious cold from noxious pressure. This ability to differentiate pains is particularly puzzling, since there is ubiquitous convergence of information from cutaneous, visceral and muscle tissue throughout the

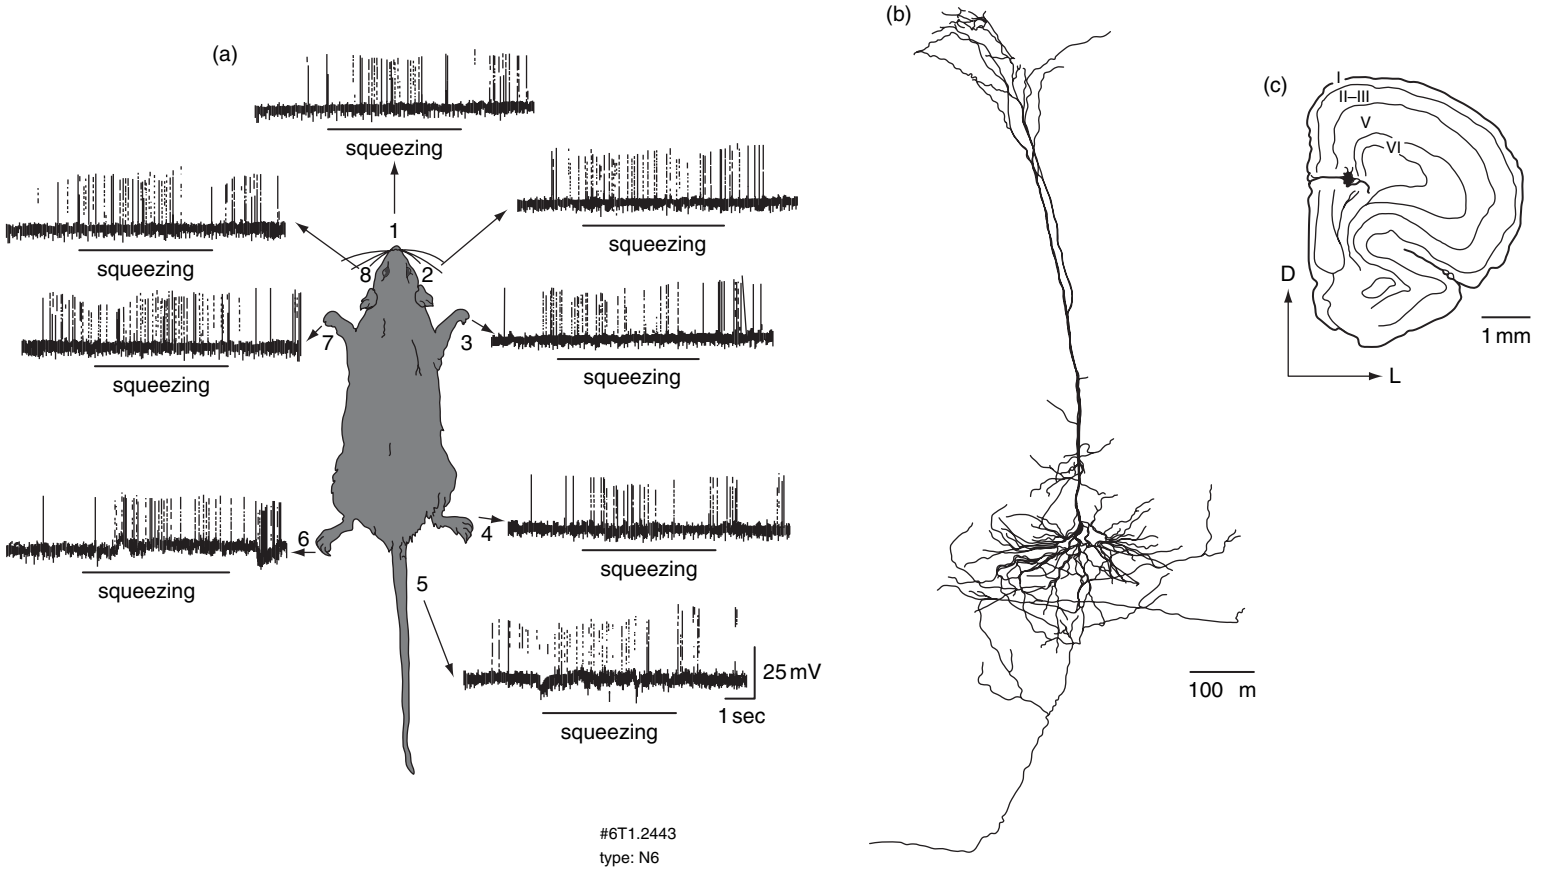

Figure 7 Nociceptive neuron in the anterior cingulate gyrus. (a) Responses to painful mechanical stimuli show a whole-body receptive field for this neuron. (b) Intracellular dye injection reveals a lamina V pyramidal neuron. (c) Location of the recorded neuron in the rat cingulate cortex. Reproduced from Yamamura, H., Iwata, K., Tsuboi, Y., Toda, K., Kitajima, K., Shimizu, N., Nomura, H., Hibiya, J., Fujita, S. and Sumino, R. 1996. Morphological and electrophysiological properties of ACCx nociceptive neurons in rats. Brain Res. 735, 83–92.

afferent nociceptive system (Willis, W. D. and Coggeshall, R. E., 2004). The convergence and the similarities in brain regions activated by different types of pain are consistent with phenomena such as referred pain, but cannot explain either the ability to identify the origin of pain or with contrasting behavioral reactions to cutaneous and visceral pain (withdrawal versus quiescence).

There is evidence from single neuron recordings, MEG, PET, and fMRI that neural activity in SI cortex could underlie the identification of the locus of cutaneous pain. Kenshalo and colleagues (Kenshalo, D. R. *et al.*, 1988; Kenshalo, D. R. and Isensee, O., 1983) showed that SI nociceptive neurons have discrete receptive fields, so that different neurons respond to painful stimulation in different skin areas. Correspondingly, EEG, PET, and fMRI studies have shown a topographic organization of nociceptive responses in SI cortex similar to the organization of tactile responses, i.e., a medio-lateral organization of foot, hand, face, and intra-abdominal areas (Tarkka, I. M. and Treede, R. D., 1993; Andersson, J. L. R. *et al.*, 1997; DaSilva, A. F. M. *et al.*, 2002; Strigo, I. A. *et al.*, 2003; Vogel, H. *et al.*, 2003). Most imaging studies find little somatotopic organization of pain in other cortical areas (Tarkka, I. M. and Treede, R. D., 1993; Xu, X. P. *et al.*, 1997), thus suggesting that responses in SI cortex may be most important for pain localization. More recently, a somatotopic organization has also been documented for operculo-insular cortex (Vogel, H. *et al.*, 2003; Baumgärtner, U. *et al.*, 2006a). A left hemisphere dominance has been reported for the sensory dimension of pain (Schlereth, T. *et al.*, 2003), whereas right hemisphere dominance was observed for the affective dimension (Pauli, P. *et al.*, 1999; Brooks, J. C. W. *et al.*, 2002).

Strigo I. A. and colleagues (2003) directly compared brain activations produced by esophageal distension and cutaneous heat on the chest that were matched for pain intensity. They found that the two qualitatively different pains produced different primary loci of activation with insula, SI, motor and prefrontal cortices. Such local differences in responses within the nociceptive network might subserve our ability to distinguish visceral and cutaneous pain as well as the differential emotional, autonomic, and motor responses associated with these different sensations.

5.45.4.2 The Time Domain

Most information about the temporal sequence of pain-evoked brain activation comes from EEG or MEG studies. The dual pain sensation elicited by a single brief painful stimulus that is due to the different conduction times in nociceptive A- and C-fibers (about 1 s difference) is reflected in two sequential brain activations in EEG and MEG recordings from SI, SII, and MCC (Bromm, B. *et al.*, 1983; Bragard, D. *et al.*, 1996; Magerl, W. *et al.*, 1999; Opsommer, E. *et al.*, 2001; Iannetti, G. D. *et al.*, 2003). EEG mapping studies (Kunde, V. and Treede, R. D., 1993; Miyazaki, M. *et al.*, 1994), source analysis (Tarkka, I. M. and Treede, R. D., 1993; Valeriani, M. *et al.*, 1996; Ploner, M. *et al.*, 1999), and intracranial recordings (Lenz, F. A. *et al.*, 1998a; Frot, M. *et al.*, 1999) show that the earliest pain-induced brain activity originates in the vicinity of SII. In contrast, tactile stimuli activate this region only after processing in the primary somatosensory cortex (Ploner, M. *et al.*, 2000). The adjacent dorsal insula is activated slightly but significantly later than the operculum (Frot, M. and Mauguière, F., 2003). These observations support the suggestion derived from anatomical studies that the SII region and adjacent insula are primary receiving areas for nociceptive input to the brain (Apkarian, A. V. and Shi, T., 1994; Craig, A. D., 2002).

5.45.4.3 Attention and Distraction Effects on Pain-Evoked Cortical Activity

Early human brain imaging studies examining the effects of attention and distraction show modulation of pain-evoked activity in a number of cortical regions, including sensory and limbic structures, as well as prefrontal areas (Bushnell, M. C. *et al.*, 1999; Longe, S. E. *et al.*, 2001; Bantick, S. J. *et al.*, 2002; Schlereth, T. *et al.*, 2003). These results generally show reduced activations in sensory regions of the cortex and some increased activity in more frontal regions, suggesting that attentional modulation is mediated through the latter structures resulting in reduced sensory processing, where the attentional distraction is usually reported resulting in reduced perceived magnitude of pain. A more recent study extends these notions by showing that during distraction there is a functional interaction between pregenual ACC and frontal cortex exerting a top-down modulation on periaqueductal gray (PAG) and thalamus to in turn reduce activity in cortical sensory regions and correspondingly decrease perception of pain (Petrovic, P. *et al.*, 2000; Tracey, I. *et al.*, 2002; Valet, M. *et al.*, 2004). Given that ACC is implicated in attentional modulation as well as pain perception, a distraction study indicates that some portions of the

pregenual ACC region are decreased with distraction while others are increased, consistent with these two different functions (Frankenstein, U. N. *et al.*, 2001).

5.45.4.4 Anticipation and Expectation

Anticipation or expectation of pain can activate many of the cortical areas related to perception of pain in the absence of a physical pain stimulus (Ploghaus, A. *et al.*, 1999; Hsieh, J. C. *et al.*, 1999b; Sawamoto, N. *et al.*, 2000; Porro, C. A. *et al.*, 2002). Two studies have attempted to identify the circuitry for modulation of pain by expectation. In one study MCC, caudate nucleus, cerebellum, and nucleus cuneiformis were modulated by systematic manipulation of pain intensity expectation by two different cues (Keltner, J. R. *et al.*, 2006), whereas pain intensity itself modulated somatosensory cortex, insula, and rostral ACC. In the second study expectancy was modulated by a placebo procedure, resulting mainly in modulation including MCC, PRC, cerebellum, pons, and parahippocampal gyrus (Kong, J. *et al.*, 2006). The latter study is complicated by the fact that the procedure is a combination of manipulation of expectancy and placebo acupuncture treatment. Generally, there remains a strong need for systematic studies to identify brain elements that modulate pain responses due to expectation.

5.45.4.5 Empathy

A provocative study opened the field regarding the interaction between pain and empathy, where the authors defined empathy as the ability to have an experience of another's pain. Using this definition and comparing brain activity for experiencing pain or knowing that their loved one, present in the same room, was experiencing the same pain, the authors showed many cortical regions similarly activated for both conditions, especially bilateral operculo-insular cortex and MCC (Singer, T. *et al.*, 2004). These results were interpreted as evidence for the affective component of pain being active in both empathy and pain, and thus concluded that empathy for pain involves the affective component, but not the sensory component, of pain. The study induced a flurry of activity in attempting to understand the relationship between empathy and pain. Multiple groups have replicated the main finding and proposed different underlying mechanisms (Morrison, I. *et al.*, 2004; Botvinick, M. *et al.*, 2005; Jackson, P. L. *et al.*, 2005), with multiple studies showing that at least MCC activity reflects the pain experienced by others and that multiple cortical areas involved in sensory processing of pain are also activated.

The overall notion that empathy involves assessment of the pain experienced by others – pain mirroring – was tested directly in subjects with alexithymia, a cognitive and emotional deficit leading to difficulty in identifying one's own emotional state and also other people's emotional state. The study showed in fact reduced activity in PRC and MCC during a pain empathy condition in this patient population (Moriguchi, Y. *et al.*, 2006). Even though these results are internally consistent, their interpretation remains problematic. Simple introspection casts doubt on the notion that empathy means actually experiencing another person's pain. Instead, what is called empathy may be the assessment of the magnitude of negative emotion that the other person may be experiencing, i.e., a cognitive function of interpersonal communication. According to that concept, empathy may be defined as a complex form of psychological inference that enables us to understand the personal experience of another person through cognitive/evaluative and affective processes. A study in patients with congenital insensitivity to pain (Danziger, N. *et al.*, 2006) reported a deficit in rating pain-inducing events, but normal inference of pain from facial expressions (empathy), indicating that empathy for pain does not require an intact pain percept.

5.45.5 Pain Modulation

5.45.5.1 Psychological Modulation of Pain

The psychological modulation of pain has been observed very early on and studied in the clinical and laboratory settings (Beydoun, A. *et al.*, 1993; Villemure, C. and Bushnell, M. C., 2002). Modern brain imaging techniques now provide powerful tools with which mechanisms of these modulations can be documented and dissected. Given that these are cognitive/attentional modulations their effects should be observed at the cortical level.

5.45.5.1.1 Hypnosis and pain-evoked cortical activity

Hypnosis can alter pain perception. It has been used to differentially modulate sensory and affective dimensions of pain and thus distinguish the cortical regions involved in these dimensions. Such studies indicate that SI activity is preferentially modulated

when the hypnotic instructions are directed to the intensity of pain, while MCC activity is preferentially modulated when hypnosis is directed to the unpleasantness of pain (Rainville, P. *et al.*, 1997, Hofbauer, R. K. *et al.*, 2001). Brain activity for hypnotically induced pain perception seem to be different from activity for imagined pain in sensory, limbic, and prefrontal activation patterns (Derbyshire, S. W. *et al.*, 2004). The sensory and limbic cortical activations for hypnotically induced and stimulation-induced pain seem relatively similar, the only region that may be differentiating them seems to be the medial PRC (Raij, T. T. *et al.*, 2005).

5.45.5.1.2 Mood and emotional states and pain-evoked cortical activity

Studies show that experimental procedures that improve mood generally reduce pain, while those that have a negative effect on mood increase pain (Zelman, D. C. *et al.*, 1991; Marchand, S. and Arsenault, P., 2002). One study showed that looking at fearful faces increased their level of anxiety and discomfort, which also resulted in enhanced esophageal stimulation-evoked activity in limbic regions like ACC and insula (Phillips, M. L. *et al.*, 2003).

5.45.5.1.3 Placebo and pain-evoked cortical activity

Placebo is a potent modulator of pain; it afflicts all clinical studies of pain pharmacology. Placebo effects have also been seen in depression and in Parkinson's disease and recent brain imaging studies show a robust brain and subcortical reward circuitry's involvement in these (Lidstone, S. C. and Stoessl, A. J., 2007). The first neurochemical evidence for opiate involvement of placebo was demonstrated about 30 years ago by showing that placebo analgesia can be blocked by naloxone (Levine, J. D. *et al.*, 1978). Consistent with this notion, changes in endogenous opiate release are shown to be involved in placebo-induced analgesia, where PRC (medial and lateral) as well as insula and ventral striatum seem to be involved, where high placebo responders increased opiate release in ventral striatum was positively correlated with pain ratings (Zubieta, J. K. *et al.*, 2005). Results generally consistent with this brain response pattern have been demonstrated by a number of other groups (Wager, T. D. *et al.*, 2004; Benedetti, F. *et al.*, 2005; Kong, J. *et al.*, 2006); the medial prefrontal/rostral ACC responses for placebo seem to recruit PAG and amygdala (Bingel, U. *et al.*, 2006); and involvement of PAG in placebo-induced analgesia is observed in the above studies as well, which links opiate descending modulation with prefrontal cortical control of placebo analgesia. The correspondence between placebo analgesia and reward was directly studied and the results show a strong correspondence between brain regions involved in each (Petrovic, P. *et al.*, 2005).

5.45.5.2 Pharmacological Modulation of Pain

A league table of analgesic efficacy has been generated based on pain-related evoked potentials (Scharein, E. and Bromm, B., 1998). Since these studies used electrical stimuli that circumvent peripheral nociceptive transduction mechanisms, this table reflects central rather than peripheral analgesic actions, as evidenced, e.g., by the higher efficacy of the antidepressant imipramine than the nonsteroidal anti-inflammatory drug (NSAID) acetylsalicylic acid. Since dipole source analysis has not been applied in these EEG studies, possible cortical sites of actions were not differentiated. Combining fMRI and pharmacology promises to provide that type of information (Tracey, I., 2001; Borsook, D. *et al.*, 2006). In addition, PET techniques can be used for direct tracing of cortical distribution of a given drug, when it has been labeled with the positron emitting ^{11}C isotope.

5.45.5.2.1 Opiates

There is a vast literature regarding opiate-mediated descending modulation through the PAG and a similarly large literature on its effects on inhibitory interneurons in the spinal cord. At the cortical level, it has been noted that opiate receptors are present in many parts of the nociceptive system, with high specific binding in ACC, insula, and frontal operculum, and with moderate specific binding in MCC, SII, and SI (Jones, A. K. P. *et al.*, 1991b; Baumgärtner, U. *et al.*, 2006a).

Recent studies of opiate-mediated responses in the brain have used two approaches, examination of metabolic function in response to pharmacological agents and direct measurement of opiate receptor binding potential. Exogenous administration of μ-opioid receptor agonist drugs show dose-dependent increased metabolic activity in regions rich with μ-opioid receptors, which in the cortex are mainly localized to PRC and ACC (Firestone, L. L. *et al.*, 1996; Schlaepfer, T. E. *et al.*, 1998; Wagner, K. J. *et al.*, 2001). Also, μ-opioid agonist fentanyl on brain responses to painful stimuli

have been explored, showing that most cortical responses to pain are reduced or eliminated, confirming analgesic effects of the opiate (Casey, K. L. *et al.*, 2000; Petrovic, P. *et al.*, 2002). Changes in endogenous opioid system is studied using a selective μ-opioid radiotracer, showing activation of opiate neurotransmission in rostral ACC, PRC, and insula during a tonic muscle pain (Zubieta, J. K. *et al.*, 2001).

5.45.5.2.2 Dopamine

Dopamine is best known for its role in motor, motivation, and pleasure control. There is accumulating evidence to suggest that dopamine acting at the level of the basal ganglia may also be involved in pain modulation. Human brain imaging studies document increased pain sensitivity to be associated with lower levels of endogenous dopamine (Pertovaara, A. *et al.*, 2004; Martikainen, I. K. *et al.*, 2005; Scott, D. J. *et al.*, 2006); and sustained experimental pain results in release of dopamine in the basal ganglia (Scott, D. J. *et al.*, 2006), and indicate an interaction between opiate activity and dopamine where alfentanil administration results in decreased mechanical pain and decreased release of dopamine in the basal ganglia (Hagelberg, N. *et al.*, 2002). Moreover, abnormal levels of dopamine in the basal ganglia have been associated with chronic pain in burning mouth syndrome and atypical facial pain (Jaaskelainen, S. K. *et al.*, 2001; Hagelberg, N. *et al.*, 2003a; 2003b), and perhaps in fibromyalgia (Wood, P. B. *et al.*, 2007). Patients with restless legs syndrome display a pronounced mechanical hyperalgesia to pinprick stimuli that is slowly reversed by dopaminergic agonists (Stiasny-Kolster, K. *et al.*, 2004), but this action is probably mediated by extrastriatal dopamine receptors.

5.45.5.2.3 Estrogen

Gender is one of the most important determinants of human health. Women far outnumber men in susceptibility to many autoimmune disorders, fibromyalgia, and chronic pain, differences in physiological responses to stress may potentially be an important risk factor for these disorders as physiologic responses to stress seem to differ according to gender, with phase of menstrual cycle, menopausal status and with pregnancy (Kajantie, E. and Phillips, D. I., 2006). Consistent with this idea recent fMRI study shows that brain activity in premenopausal women as studied for negative valence/high arousal in contrast to neutral visual stimuli show differences when the task is performed during early follicular menstrual cycle phase compared to late follicular/mid-cycle; with greater activity found during early follicular phase in amygdala, hypothalamus, hippocampus, orbital frontal cortex, and ACC, suggesting that estrogen may attenuate arousal in women through cortical-subcortical control of hypothalamic–pituitary–adrenal circuitry (Goldstein, J. M. *et al.*, 2005). There is also growing evidence of gender differences in the anatomy of the brain, its connectivity, and in cognitive abilities (Hampson, E., 2002; Becker, J. B. *et al.*, 2005). Multiple studies have documented that threshold and tolerance for pain is lower for women (Wiesenfeld-Hallin, Z., 2005; Rolke, R. *et al.*, 2006; Wilson, J. F., 2006).

Gender differences in cortical activity for acute pain has been observed in early studies (Paulson, P. E. *et al.*, 1998). The association of sex hormones with pain perception and pain memory was studied by Zubieta J. K. and colleagues (Zubieta, J. K. *et al.*, 2002; Smith, Y. R. *et al.*, 2006). They scanned healthy women during their early follicular phase when estrogen levels are low and then repeated the scan during that same phase in another month after they had worn for a week an estrogen-releasing skin patch which increased their estrogen to levels normally seen in the menstrual cycle. These studies showed that more μ-opioid receptors were available in the presence of high estrogen levels, and women reported less pain in response to acute painful stimuli than when their estrogen levels were low. Moreover, estrogen-associated variations in the activity of μ-opioid neurotransmission correlated with individual ratings of the sensory and affective perceptions of pain and the subsequent recall of that experience. These data demonstrate a significant role of estrogen in modulating endogenous opioid neurotransmission and associated psychophysical responses to an acute pain stressor in humans. Approximately similar results have been reported by another group (De Leeuw, R. *et al.*, 2006).

5.45.6 Overview Regarding the Role of the Cortex in Acute Pain Perception

The above sections describe the contribution of modern imaging studies to our understanding of the involvement of the cortex in pain perception. Cortical activity is demonstrated to possess properties necessary for involvement in pain perception, like somatotopic representation of painful stimuli,

correlation with stimulus intensity, modulation with attention, modulation with expectation and other psychological variables, and distinct brain regions showing differential activity for sensory and affective dimensions of pain, as well as attenuation of responses with analgesic drugs (Apkarian, A. V. *et al.*, 2005). Thus, human brain imaging studies have asserted the role of the cortex in acute pain.

However, because imaging studies identify brain responses in a correlative manner, they may all reflect secondary processes. Perception of pain automatically directs attention to the source of pain, results in autonomic responses, motor reflexes to escape from the pain, and other emotional and cognitive responses that undoubtedly are at least partially mediated through cortical processes. Therefore, the role of the cortex in pain perception in contrast to its activity as a consequence of these secondary responses remains unclear and needs to be properly addressed in future studies (Apkarian, A. V., 2004).

In fact, unpublished data from Apkarian's laboratory suggest that a large proportion of the brain network activated with acute pain may be responses that are commonly involved in general magnitude estimation for any sensory modality, and as a result are not specific for nociception (abstract Society for Neuroscience 2006), suggesting that the majority of cortical activity for acute pain are instead sensory, cognitive, emotional, and attentional responses to nociceptive inputs. Careful clinical and neuropsychological examination of patients with small brain lesions, combined with high-resolution structural and neuropharmacological neuroimaging in the same patients, will be needed to address the question what brain structures are necessary for acute pain perception. Anatomical tracing studies and single unit recordings should address the question, to what extent nociceptive specific neurons exist in these brain structures. For most parts of the nociceptive cortical network, as illustrated above, it is likely that they participate only partly in pain perception, by providing certain feature extraction functions, but they also participate in other functions in different contexts.

5.45.7 Clinical Applications

It should be emphasized that although the subjective phenomenon of being in pain can be considered an emergent phenomenon of cortical activity (Treede, R. D., 2001), there is currently no measure of brain activity that would objectively show whether or not a person is in pain. Therefore, neither EEG/MEG nor imaging with fMRI or PET can be used to verify the presence of ongoing spontaneous pain.

EEG and MEG recordings of evoked potentials, however, are sensitive enough to verify whether the ascending nociceptive pathways are intact in a given individual patient (Bromm, B. and Lorenz, J., 1998; Treede, R. D. *et al.*, 2003; Cruccu, G. *et al.*, 2004). A prerequisite for this use of EEG and MEG technology is a phasic adequate stimulus for nociceptor activation. Radiant heat pulses of a few milliseconds duration, as generated by infrared lasers, have been validated for this purpose (Plaghki, L. and Mouraux, A., 2003), and LEPs can thus be used to verify the presence of negative sensory signs of nociception (hypoalgesia).

Neither fMRI nor PET are sensitive enough to allow clinical assessment of nociceptive pathways in individual cases, since so far no activation paradigm has been developed that would reliably induce a particular cortical activation pattern in each and every healthy subject. Thus, negative findings with these techniques are inconclusive.

For the study of pathological nociceptive processing at the group level, however, fMRI and PET techniques are extremely powerful. These techniques have broadened our understanding of the pathophysiology of conditions with decreased pain perception such as afferent pathway lesions or borderline personality disorder, and conditions with increased pain perception such as neuropathic pain or fibromyalgia (Gracely, R. H. *et al.*, 2004; Maihöfner, C. *et al.*, 2005; Garcia-Larrea, L. *et al.*, 2006; Schmahl, C. *et al.*, 2006; Schweinhardt, P. *et al.*, 2006). In addition, PET allows direct estimation of pharmacological and biochemical processes in the brain, such as alterations in dopamine or opioid receptor availability (Hagelberg, N. *et al.*, 2003a; Willoch, F. *et al.*, 2004).

5.45.8 Chronic Pain

5.45.8.1 Studying Brain Activity in Chronic Pain with Nonspecific Painful Stimuli

Chronic pain might result from cortical processing of chronic nociceptive spinothalamic input according to the same mechanisms as in acute pain, or there might be specific changes in cortical processing of nociceptive input in patients with chronic pain. Such changes

could then either be a causal factor for or a consequence of the chronicity of the pain condition.

A recent meta-analysis in fact shows that across some 100 studies one can establish statistically significant differences in incidence of different brain areas activated by experimental painful stimuli between acute and chronic pain conditions: PRC shows a stronger activation in chronic pain patients, whereas other nociceptive cortical areas and the thalamus show a weaker response (Table 2). A simple interpretation of these findings would be that nociceptive signal processing for experimental painful stimuli in chronic pain patients involves a reduced sensory discriminative component and an increased affective-motivational or cognitive-evaluational component. That interpretation would also be consistent with the stronger affective component of clinical pain as compared to experimental pain (Chen, A. C. N. and Treede, R. D., 1985). But there are further implications: Is the result a consequence of some trivial confounds or does it signify changes in the physiology of pain? One could construct a long list of confounds that may underlie the observation, from attentional shifts, to coping mechanisms, to effects of drug use, and heightened anxiety and depression.

The standard approach for studying brain activity for acute pain is to induce pain by a mechanical or thermal stimulus and determine brain regions modulated with the stimulus period and even with the various intensities used. Therefore, it is natural to carry the same technology to the clinical arena and apply it to chronic pain patients. As an example, we discuss one study which attempted to identify brain activity in complex regional pain syndrome (CRPS) patients using fMRI (Apkarian, A. V. *et al.*, 2001a; 2001b).

The design of the study was to examine brain activity for thermal stimuli applied to the body part where CRPS pain was present, and compare brain responses to this stimulus between CRPS and healthy subjects. Moreover, as the pain in CRPS patients with sympathetically maintained pain (SMP) may be modulated by a sympathetic block, it was reasoned that one could decrease the patients' ongoing pain and then re-examine brain activity responses to the same stimulus. The study was done in a small group of patients and this by itself is an important weakness. The main observation was that thermal stimuli in CRPS evoked more prefrontal cortical activity than usually seen in healthy subjects, and this was reversed (became more similar in pattern to normal subjects' brain activity to thermal stimuli) following sympathetic blocks. The introduction of sympathetic blocks necessitated the use of the same procedure in healthy subjects as well, where its effects were minimal. The study also observed that when a placebo block resulted in decreased pain perception then the cortical response pattern changed similarly to that of effective blocks. These results show that brain activity may be distinct between CRPS and healthy subjects for thermal stimuli.

5.45.8.2 Clinical Pain Conditions Studied by Stimulation and the Role of the Cortex

A direct approach to studying clinical pain states is to provoke it and examine brain activity. This is doable by drugs in headaches and in cardiac pain. As a result there is growing literature in both fields. There is also now good evidence that migraine with aura is accompanied with decreased blood flow and decreased activity in the occipital cortex, and migraine with or

Table 2 Frequency of brain areas active during pain in normal subjects as compared to patients with clinical pain conditions

	ACC	*SI*	*SII*	*IC*	*Th*	*PFC*
Pain in normal subjects in 68 studies	47/54 (87%)	39/52 (75%)	38/51 (75%)	45/48 (94%)	28/35 (80%)	23/42 (55%)
Clinical pain conditions in 30 studies	13/29 (45%)	7/25 (28%)	5/25 (20%)	15/26 (58%)	16/27 (59%)	21/26 (81%)
Comparison between pain in normal subjects and in clinical conditions	$P < 0.001$	$P < 0.001$	$P < 0.001$	$P < 0.001$	$P = 0.095$	$P = 0.038$

Incidence values are based on positron emission tomography, single photon emission-computed tomography, and functional magnetic resonance imaging studies. For details see Apkarian *et al.*, 2005. P values are based on Fisher's exact statistics contrasting incidence for each area. ACC, anterior cingulate cortex; IC, insular cortex; PFC, prefrontal cortex; SI, primary somatosensory cortex; SII, secondary somatosensory cortex; Th, thalamus.

without aura is associated with increased cortical thickness in visual cortical regions involved in motion detection (Granziera, C. *et al.*, 2006).

5.45.8.2.1 Migraine

Migraine attacks are characterized by unilateral severe headache often accompanied by nausea, phonophobia and photophobia. Activation of the trigeminovascular system is thought to be responsible for the pain itself, and cortical spreading depression (CSD) seems to underlie the aura symptoms. This view has been greatly advanced and substantiated by brain imaging studies. fMRI studies show CSD-typical cerebrovascular changes in the cortex of migraineurs while experiencing a visual aura (Hadjikhani, N. *et al.*, 2001). The subsequent decrease in fMRI signal is temporally correlated with the scotoma that follows the scintillations. These fMRI signal changes develop first in the extrastriate cortex, contralateral to the visual changes. It then slowly migrated towards more anterior regions of the visual cortex, representing peripheral visual fields, in agreement with the progressive movement of the scintillations and scotoma from the centre of vision towards the periphery. A recent study that analyzed visually triggered attacks showed hyperemia in the occipital cortex, independently of whether the headache was preceded by visual symptoms (Cao, Y. *et al.*, 1999). An alternative view considers migraine aura and headache as parallel rather than sequential processes, and proposes that the primary cause of migraine headache is an episodic dysfunction in brainstem nuclei that are involved in the central control of nociception (Goadsby, P. J. *et al.*, 2002).

5.45.8.2.2 Cluster headache

The pathophysiology of cluster headache is thought to involve multiple brain regions. Brain imaging studies imply that the associated excruciatingly severe unilateral pain is likely mediated by activation of the first (ophthalmic) division of the trigeminal nerve, while the autonomic symptoms are due to activation of the cranial parasympathetic out-flow from the VIIth cranial nerve. The circadian rhythmicity of cluster headache has led to the concept of a central origin for its initiation (Strittmatter, M. *et al.*, 1996).

Using PET in cluster headache patients, significant activations ascribable to the acute cluster headache were observed in the ipsilateral hypothalamic gray matter and in multiple cortical areas including cingulate and PRC. When compared to the headache-free state only hypothalamic activity was distinct (May, A. *et al.*, 2000). This highly significant activation was not seen in cluster headache patients out of the bout when compared to the patients experiencing an acute cluster headache attack. In contrast to migraine, no brainstem activation was found during the acute attack compared to the resting state. Newer MRS results further substantiate this idea by showing reduced metabolites within the hypothalamus of cluster headache patients in contrast to healthy or migraine headache controls (Wang, S. J. *et al.*, 2006). These data suggest that while primary headaches such as migraine and cluster headache may share a common pain pathway, the trigeminovascular innervation, and activate similar cortical regions, the underlying pathogenesis may be quite different.

5.45.8.2.3 Cardiac pain

Cardiac pain and its variants have been studied by brain imaging using various drugs that bring about these symptoms (Rosen, S. D. *et al.*, 1996; 2002). In patients with myocardial ischemia the perception of angina is associated with activity in the hypothalamus, PAG, thalami, rostral ACC, and bilateral PRC. In patients with silent myocardial ischemia it seems that the silence is not due to impaired afferent signaling, but rather it is associated with a failure of transmission of signals from the thalamus to the frontal cortex. In contrast, in patients with syndrome X, a condition of chest pain with ischemiclike stress electrocardiography but entirely normal coronary angiogram, activity in the right anterior insula distinguished these patients from patients with known coronary disease. These patients appear to have a deficit in central pain habituation (Valeriani, M. *et al.*, 2005). Overall, these studies imply that difference between different cardiac pain conditions are due to central processing, e.g., syndrome X is interpreted as a cortical pain syndrome, a top-down process, in contrast with the bottom-up generation of a pain percept caused by myocardial ischemia in coronary artery disease.

5.45.8.2.4 Irritable bowel syndrome

Irritable bowel syndrome (IBS) is a disorder of abdominal pain or discomfort associated with bowel dysfunction. Hypersensitivity to visceral, but not somatic, stimuli has been demonstrated in IBS. A number of groups have examined brain activity in this condition mainly by monitoring responses to

painful and nonpainful rectal distensions, as well as responses to the anticipation of painful distensions. Two studies are interesting since both show in normal subjects a significant positive correlation between cingulate cortex activity and subjective rating of rectal distension pain, and in both studies this relationship completely disappears in IBS patients (Silverman, D. H. *et al.*, 1997; Mertz, H. *et al.*, 2000). IBS is more prevalent in women than in men. Brain imaging studies have now shown gender differences in brain activity in IBS (Berman, S. M. *et al.*, 2000; Naliboff *et al.*, 2001; Berman, S. M. *et al.*, 2002b; Nakai, A. *et al.*, 2003). There are large differences between the studies, making their synthesis difficult (see Ringel, Y., 2006).

More recent studies show a hint for sensitization in IBS patients because subliminal and supraliminal distensions of rectal distension seem to indicate small differences between IBS and healthy controls in the total cortical volume activated or in regional activity as a function of distention volume (Andresen, V. *et al.*, 2005; Lawal, A. *et al.*, 2006). A study of IBS in contrast to healthy subjects examined thermal and visceral hyperalgesia and related brain activity (Verne, G. N. *et al.*, 2003). This seems the only study where besides pain intensity and unpleasantness measures, the authors also document fear and anxiety and show that all are rated higher by IBS for both heat and rectal distention, and not surprisingly these increased sensations and emotions give rise to larger cortical activations in IBS. The latter is most likely a reflection of a perceptual magnitude mismatch between the groups and says little as to the IBS cortical activity abnormalities. Such mismatches at least for fear and anxiety most likely are common in the majority of studies of IBS. One assumes that the simple introduction of a rectal balloon in IBS would result in increased anxiety, which undoubtedly effects cortical activity to visceral and somatic pain, yet its specific contribution has remained unexplored.

In a more elegant study the authors use perception-related ratings during rectal distention to evoke either urge to defecate or pain, and compared brain activity related to the ratings between IBS patients and healthy subjects. (Kwan, C. L. *et al.*, 2005). The approach is similar to the technique used in mapping brain activity for spontaneous pain in chronic back pain (CBP) and in postherpetic neuralgia (PHN; Baliki, M. N. *et al.*, 2006; Geha, P. Y. *et al.*, 2007). The results show large differences between the two groups contrasted, with far more extensive brain activations in the healthy subjects. The results are complicated by the fact that the authors do not take into consideration the influence of spontaneous pain. Still, this is perhaps one of the best-controlled IBS studies, and indicates distinct cortical areas involved in the urge and pain perceptions in each group.

There is now evidence that serotonin (5-HT) may be involved in IBS. One study (Nakai, A. *et al.*, 2003) examined serotonin synthesis in the brain and indicated greater brain regional serotonin synthesis in female IBS. There is also evidence that alosetron, a 5-HT_3 receptor antagonist, is clinically effective in treating some subtypes of IBS. Berman S. M. *et al.* (2002a) examined brain activity in a large population of IBS, before and after a randomized, placebo-controlled, 3-week use of alosetron. Treatment improved IBS symptoms and regional cerebral blood flow in brain regions rich with 5-HT_3 receptor and involved in emotional and aversive functions: amygdala, ventral striatum, and dorsal pons, implying that the therapeutic effects are due to central actions and not peripheral. Thus, generally the IBS studies show that brain responses are different to rectal stimuli in patients, and that these central events may be critical to IBS.

5.45.8.3 Spontaneous Pain as a Confound in Assessing Brain Activity

A person who has lived for years in the presence of pain, must have developed some coping mechanisms that aid in pursuing other everyday life interests in spite of the presence of the pain. How does this impact the brain? Can one consider the patient in chronic pain as composed of a brain-signaling pain together with a brain undertaking other tasks as in healthy subjects? Or, does the presence of ongoing pain interact and impact other processes as well? Certainly our cognitive and anatomic studies suggest that the latter is more likely. We have now direct evidence of the modulation that ongoing pain imposes on brain activity in general.

A recent study reported brain activity for spontaneous pain in PHN patients before and after topical lidocaine treatment (Geha, P. Y. *et al.*, 2007). The PHN patients were imaged before, after 6-hours and 2-weeks treatment with lidocaine. Behaviorally and based on questionnaires most participants showed a modest but significant decrease in their ongoing pain. The patients were scanned while they were either rating their ongoing pain or rating a visual bar that varied in time in a pattern that mimicked their ratings of pain (Figure 8). Thus, the

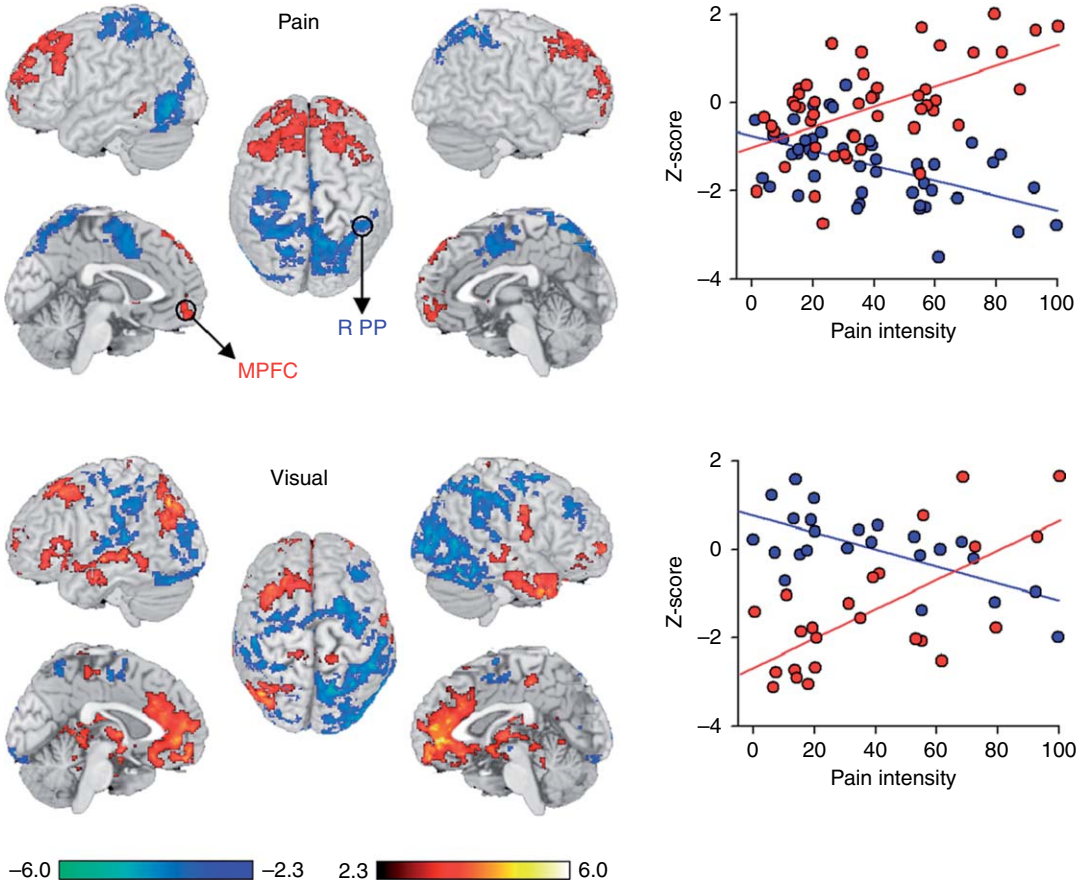

Figure 8 Intensity of ongoing pain changes brain activity and thus cognitive processing. Eleven postherpetic neuralgia patients were studied by functional magnetic resonance imaging (fMRI) once before and twice after lidocaine application on the painful skin. In all sessions, patients performed two different tasks: in the Pain task they continuously rated the fluctuations of their spontaneous pain, and brain activity related to this was identified using methods. In the Visual task they rated fluctuations of a bar varying in time, brain activity was determined with the same approach as for the pain task. The relationship between brain activity and intensity of ongoing pain was determined by using a covariate analysis, where for each fMRI scan its related pain intensity was used to determine the effect of this parameter on brain responses. Across-subject and across all scans average variation of brain activity is displayed for both tasks in the left. Red are brain regions that are positively correlated and blue regions that are negatively correlated with intensity of ongoing pain (normalized to z-values). The right scatter-grams show this effect for two brain regions (right posterior parietal cortex, R PP, $x = 33$ $y = -45$ $z = 50$; and medial prefrontal cortex, MPFC, $x = 9$ $y = 50$ $z = -40$, as respectively circled). Each dot represents a single patient's activity at a single time. Top scatter-gram is for Pain task; bottom for Visual task, red symbols and regression line are for MPFC; blue for R PP. MPFC exhibited significant positive correlations with pain intensity for pain ($r = 0.49$, $P < 0.05$) and visual ($r = 58$, $P < 0.01$) task, while R PP showed negative correlation for pain ($r = -0.48$, $P < 0.05$) and visual ($r = -0.64$, $P < 0.01$) task. Brain areas that show increased correlation with ongoing pain are interpreted as a functional compensation for the decreased attentional resources. Reproduced from Geha, P. Y., Baliki, M. N., Chialvo, D. R., Harden, R. N., Paice, J. A., and Apkarian, A. V. 2007. Brain activity for spontaneous pain of postherpetic neuralgia and its modulation by lidocaine patch therapy. Pain 128, 88–100.

latter is a control task that captures motor and cognitive parts of the task but, of course, it does not reflect the pain. Brain activity for both tasks was increasing from first to third session. This observation is similar to earlier reports that decrease in clinical pain in many cases results in increased brain activity. In this case, however, the internal control was also changing in a manner parallel to the pain condition, hinting that the effects of decreased pain was modulating more than just pain-related circuitry.

To identify the role of spontaneous pain on brain activity in general, a correlation analysis was done for both tasks with mean spontaneous pain. Figure 8 shows the influence of pain intensity on across-sessions averaged brain activity for both tasks.

The resultant map is generally similar for both tasks: activity in medial and lateral prefrontal regions was positively correlated, while posterior parietal attentional areas were negatively correlated with mean pain intensity. This result shows that brain activity for both tasks is influenced by the level of spontaneous pain, implying that pain intensity influences task performance in general. This is in line with previous studies showing that ongoing pain may interfere with cognitive functions (Lorenz, J. *et al.*, 1997).

This result reinforces the need for correcting brain activity by a control condition performed at the same pain level that is the necessity of subtracting the visual task from spontaneous pain rating task, at each treatment session. For both tasks, the fact that posterior parietal cortical activity was negatively correlated with mean ongoing pain suggests that the attentional abilities of patients are directly related to the intensity of their pain, which would in turn impact their abilities in performing anything that would demand concentration.

Moreover, multiple prefrontal regions were positively correlated to the mean pain, suggesting that the patients' brain regions underlying higher cognitive functions become more active as the pain intensity increases. The exact cognitive implications for these brain activity patterns remain unclear. In contrast, the finding indicates that the intensity of spontaneous pain impacts brain activity for any task that the subject attempts to perform, enhancing some aspects and inhibiting others. Therefore, the decreased brain activity reported for pain tasks in many clinical pain conditions (Peyron, R. *et al.*, 2000; Derbyshire, S. W., 2003; Apkarian, A. V. *et al.*, 2005; Kupers, R. and Kehlet, H., 2006) is most likely a reflection of the presence of the spontaneous pain, and is not specific to the task being investigated.

The fact that pain intensity seems to modulate brain activity in general has another powerful consequence. It suggests that simply studying brain activity, in tasks unrelated to pain, one should be able to identify the presence of pain and study its effects on sensory/cognitive/motor/attentional processing, an exciting prospect that remains to be pursued.

5.45.8.4 Functional Magnetic Resonance Imaging of Spontaneous Pain

Spontaneous pain is highly prevalent in clinical pain conditions, and is usually the primary drive for patients seeking medical care. Thus, understanding its related brain circuitry is both scientifically and therapeutically imperative. Cortical responses to standard mechanical or thermal stimulation are of limited value for understanding these clinical pain conditions. Spontaneous pain fluctuates unpredictably in the time scale of seconds to minutes, and these fluctuations have characteristic properties that differentiate between different chronic pain conditions such as PHN and CBP (Foss, J. M. *et al.*, 2006). This variability (specific fractal dimension) can also be observed in fMRI signals when such patients rate their spontaneous pain. Therefore, this technique was applied to study brain activity in CBP (Baliki, M. N. *et al.*, 2006) and PHN patients (Geha, P. Y. *et al.*, 2007) in relation to their subjective report of fluctuations of spontaneous pain.

The combination of relating brain activity to spontaneous pain and correcting for confounds by subtracting brain activity for visual bar lengths, provides a robust approach with which clinical pain may be studied directly. Note that in this case the brain activity is related to exactly the event that the patient complains about. With this approach, in CBP patients (Baliki, M. N. *et al.*, 2006) it was shown that the brain regions activated when the pain was increasing correspond to brain regions seen for acute pain in normal subjects. In contrast, for time periods when the pain was high and sustained, the brain activity was mainly limited to medial PRC, a region usually not activated for acute pain. The resultant brain activity was strongly correlated to the patients' reported pain intensity at the time of the scan, specifically with medial prefrontal activity. Also, the duration or chronicity of the pain was captured in the insular activity, a region activated only during increases in spontaneous pain. Thus, two fundamental properties of CBP its intensity and duration were directly reflected in the brain activity identified in these patients. By applying a thermal painful stimulus in the same patients (as well as in healthy subjects) the same study showed that brain regions reflecting the stimulus intensity were not related to that reflecting the intensity of spontaneous pain. In turn, the brain region that reflected spontaneous pain intensity was only activated for the latter and did not reflect thermal painful stimulus intensity. Therefore, at least in the patient group studied spontaneous pain involved a different brain activity pattern than acute pain.

5.45.8.5 Neuropathic Pain

Patients with neuropathic pain show decreased responses in the thalamus to experimental painful

stimuli (Peyron, R. *et al.*, 2000). A MRS study showed a decrease in the level of *N*-acetyl-aspartate, a neuronal marker, in the thalami of patients with chronic neuropathic pain after spinal cord injury (SCI), when compared to patients with SCI but without pain (Pattany, P. M. *et al.*, 2002). Thus, neurochemical brain imaging provides evidence for the occurrence of long-term changes in the brain chemistry and morphology of chronic neuropathic pain patients. Thalamic activity in neuropathic patients was also reported to increase after pain relief (Hsieh, J. C. *et al.*, 1995), and to be significantly negatively correlated with the duration of the condition in CRPS patients (Fukumoto, M. *et al.*, 1999). Thus, the reduced activation of the thalamus may also be an altered functional state rather than an irreversible degeneration. Neuropathic pain patients in addition show a reduced availability of opioid receptor binding sites (Maarrawi, J. *et al.*, 2007). This reduction was symmetric in peripheral neuropathic pain, suggesting a possible release of endogenous opioids, but lateralized to the hemisphere contralateral to the pain in central pain patients, consistent with a loss of receptors (Jones, A. K. P. *et al.*, 2004, Willoch, F. *et al.*, 2004).

Brain activity differences between healthy subjects and patients in activation paradigms are difficult to interpret since they do not distinguish between brain activity specifically related to the clinical condition and abnormalities in sensory processing secondarily associated with the clinical state. Particularly in neuropathic pain, the accompanying sensory deficit may be reflected in the imaging results and not the pain. Reduced relevance of the acute stimulus to subjects who are already in pain may also account for much of the decreased regional brain activity in neuropathic pain. To overcome such nonspecific brain activity differences one needs to compare brain activity for stimuli where perceptual evaluation has been equated between patients and normal healthy subjects.

Three studies (Hsieh, J. C. *et al.*, 1995; 1999a; Apkarian, A. V. *et al.*, 2001b) have looked at the regions of the brain modulated by relief of chronic neuropathic pain: CRPS, peripheral neuropathy, and trigeminal neuropathy. Two of these studies show that the PRC activity is decreased, and all three studies report decreased rostral ACC activity, after successful pain relief. It is to be noted that in addition to those regions some areas were also less activated with pain relief such as the insula (Hsieh, J. C. *et al.*, 1995) and the anterior limbic thalamus (Hsieh, J. C. *et al.*, 1999a), whereas others were more activated after pain relief like the medial PRC (Hsieh, J. C. *et al.*, 1999a). This heterogeneity is not surprising because pattern of brain activity may be specific to each neuropathic pain condition.

5.45.8.6 Low Back Pain and Fibromyalgia

As mentioned above, brain activity of healthy subjects and patients with increased pain sensitivity should be compared in such a way that perceived intensity has been matched across the two groups. A recent study used such a design and showed generally heightened brain activity for painful stimuli of equivalent perceptual intensity both in fibromyalgia and CBP patients as compared to healthy subjects (Gracely, R. H. *et al.*, 2002; Giesecke, T. *et al.*, 2004). Morphometric and neurochemical brain imaging studies provide evidence for the occurrence of long-term changes in the brain chemistry and morphology of chronic pain patients. The level of *N*-acetyl-aspartate, a neuronal marker, was decreased in the medial and lateral PRC of CBP patients compared to an age- and gender-matched control group (Grachev, I. D. *et al.*, 2000). A morphometric study in chronic pain showed also a decrease in gray matter density in the dorsolateral PRC and the thalamus of CBP patients when compared to matched controls (Apkarian, A. V. *et al.*, 2004). Furthermore, these long-term chemical and morphological changes are significantly correlated with different characteristics of pain such as pain duration (Apkarian, A. V. *et al.*, 2004), pain intensity (Pattany, P. M. *et al.*, 2002; Grachev, I. D. *et al.*, 2002; Apkarian, A. V. *et al.*, 2004), and sensory-affective components (Grachev, I. D. *et al.*, 2002). The morphometric and neurochemical studies imply an active role of the central nervous system in chronic pain, suggesting that supraspinal reorganization may be critical for chronic pain.

5.45.8.7 Overview Regarding the Role of the Cortex in Chronic Pain Perception

In spite of a plethora of data there remains a host of uncertainties about their significance. Overall, the clinical brain imaging studies indicate reduced information transmission through the thalamus to the cortex, and increased activity in PFC, mostly in medial PFC coupled with atrophy in dorsolateral PFC. The number of studies remain very small and hence our confidence as to the reproducibility of these changes remain minimal. Still, the observations

regarding cortical and thalamic activity changes in chronic pain are in general consistent with the notion that chronic pain conditions preferentially engage brain areas involved in cognition/emotion and decreases activity in regions involved in sensory evaluation of nociceptive inputs.

Evidence has been presented that brain activity, chemistry, and morphology may be reorganized in chronic pain conditions. Does this evidence imply that there is supraspinal reorganization, above and beyond what is established in the periphery and spinal cord? That is, even if we establish a brain pattern of activity for some chronic pain condition, does this reflect some unique contribution of the brain to this state or is it simply a reflection of lower level reorganization? The answer is not straightforward. However, only by answering such questions will brain imaging be able to provide new information to the myriad mechanisms described for peripheral and spinal cord reorganization in chronic pain.

5.45.9 Conclusions and Outlook

The study of nociceptive processing in the cerebral cortex has come a long way. In contrast to earlier assumptions, the classical somatosensory cortex areas are not the only ones activated by painful stimuli. In addition, limbic areas such as the anterior and midcingulate cortex and the insula have also been recognized as part of the nociceptive network, and more recently also cognitive areas in the PRC. Limbic areas are usually considered to mediate emotional processes, but they are also involved in autonomic and motor functions. In this way, progress in understanding the cortical nociceptive network mirrors that in understanding the subcortical networks, which also include many connections to autonomic and motor nuclei as well as hypothalamus, cerebellum, and basal ganglia. Images of brain activation by painful stimuli leave the impression that at least half of the brain participates in processing nociceptive information. At other times, many of the same areas participate in visual, motor, emotional, cognitive, or other signal processing. In that sense, our current understanding of the nociceptive network in the brain is consistent with our current understanding of how the brain uses distributed processing for its many functions. It is not clear, however, to what extent any part of the cerebral cortex is specific for nociception. The best candidate region for such a function lies in the parasylvian cortex, in the vicinity of SII and the dorsal insula. In chronic pain, nociceptive processing in the cerebral cortex is partly preserved and partly altered, in particular with respect to PRC functions. This reorganization may be a neuroplastic response to the chronicity of pain, it may reflect activation of antinociceptive processes, or it may even represent a predisposing factor for the development of chronic pain. The methods available for the study of nociceptive processing in the brain allow to address many of these open questions in the near future, and this part of pain research is bound to remain a very productive one.

Glossary

cortical reorganization Changes in the maps of the primary sensory or motor areas of the cortex related to injury or stimulation. Cortical representations can increase or decrease in size or they can shift to other locations on the sensory or motor map.

central sensitization Short- or long-term changes in the excitability of central neurons and their synaptic strength that lead to an enhanced or altered processing of peripheral sensory input resulting in hypersensibility.

neuroma When a limb is severed, a terminal swelling or endbulb is formed with axonal sprouting occurring. In the case of an amputation this sprouting and endbulb formation lead to neuroma, a tangled mass that is formed when the axons cannot reconnect or can only partially reconnect as is the case in partial lesions. These neuroma generate abnormal activity that is called ectopic because it does not originate from the nerve endings.

nonpainful phantom limbs and nonpainful phantom sensations These phenomena refer to the continued presence of the limb (corporeal awareness of the limb) and nonpainful sensations such as tingling or pressure sensations.

nonpainful residual limb sensations The residual limb can also have nonpainful sensations such as tingling or cramping sensations that can be distinguished from phantom sensation as well as from painful sensation.

phantom limb pain or phantom pain Pain in a body part that is no longer present. It may be related to a certain position or movement of the phantom and may be elicited or exacerbated by a range of physical (e.g., changes in weather or pressure on the residual limb) and psychological factors (e.g., emotional stress). It seems to be more intense in the distal portions of the phantom and may have a number of different qualities such as stabbing, throbbing, burning, or cramping. Phantom limb pain is often confused with pain in the area adjacent to the amputated body part.

postamputation pain Pain at the site of the wound that must be distinguished from pain in the residual limb and phantom limb pain that may all co-occur in the early phase after amputation.

preamputation pain Pain that occurred in the amputated body part before the amputation. It may be related to the incidence, type, and severity of phantom limb pain in the phase following the amputation.

residual limb pain or stump pain Pain in the body part adjacent to the amputation. It is usually positively correlated with phantom limb pain.

5.46.1 Definition

The amputation of a body part is often followed by the sensation that the deafferented body part is still present. These sensations may include not only the feeling of the continued presence of the limb but also nonpainful and painful phantom sensations such as the feeling of a specific position, shape, or movement of the missing limb, feelings of warmth or cold, itching, tingling or electric sensations, and other paresthesias.

Phantom limb pain (or phantom pain) is pain in the body part that is no longer present. This occurs to some degree in 50–80% of all amputees (Nikolajsen, L. and Jensen, T. S., 2006). Phantom limb pain may be related to a certain position or movement of the phantom and may be elicited or exacerbated by a range of physical (e.g., changes in weather or pressure on the residual limb) and psychological factors (e.g., emotional stress). It seems to be more intense in the distal portions of the phantom and may have a number of different qualities such as stabbing, throbbing, burning, or cramping (Hill, A., 1999). Phantom limb pain belongs to the neuropathic pain syndromes and is assumed to be related to damage to the axons of peripheral neurons with secondary changes induced in central neurons. Phantom body pain may also occur following spinal cord injury. Phantom limb pain is infrequent if the amputation occurred at a very young age. However, older children exhibit as high an incidence of phantom limb pain as adults. Although phantom sensations seem to occur occasionally in congenital amputees (i.e., those born without a limb), phantom limb pain seems to be very rare under these circumstances (Flor, H., 2002). The long-term course of phantom limb pain is unclear. While some authors report a slight decline in pain prevalence over the course of several years, others have described high prevalence rates also in long-term amputees. Both peripheral and central factors have been discussed as determinants of phantom limb pain. Psychological factors do not seem to be a primary cause, but they may well affect the course and the severity of the pain (Sherman, R. A., 1997). The general view today is that multiple changes along the neuraxis contribute to the experience of phantom limb pain.

5.46.2 Peripheral Mechanisms of Phantom Limb Pain

Peripheral changes that give rise to nociceptive input from the residual limb have been viewed as an important determinant of phantom limb pain. This is supported by the moderately high correlation between pain in the residual limb (stump) and phantom limb pain. Ectopic discharge from stump neuromas has been postulated as a potential source of such nociceptive input (Devor, M., 2006). When peripheral nerves are cut or injured, terminal swelling and regenerative sprouting of the injured axon end occur. In this process, neuromas form in the residual limb. The disorganized endings of C fibers and demyelinated A fibers in neuromas have increased excitability and often show spontaneous impulse activity (ectopic discharge). Mechanical, chemical, and thermal stimulation may further exacerbate this ectopic discharge. The increased excitability of injured nerves that results in ectopic discharge seems to result from upregulation or novel expression, and altered trafficking, of molecules that are responsible for neuronal excitability, such as voltage-sensitive sodium channels (Devor, M., 2006). In addition, abnormal connections between injured axons, such as ephapses, may contribute to the spontaneous ectopic activity. Phantom limb pain is often present very soon after amputation before a palpable, swollen neuroma could have formed. However, ectopic discharge also appears rapidly, apparently originating at first in swollen endbulbs at the cut axon end rather than in outgrowing sprouts.

Local anesthesia of the stump does not eliminate phantom limb pain in all amputees (Birbaumer, N. *et al.*, 1997). This fact motivated a search for other potential sources of ectopic input from the periphery. An additional site of ectopic discharge is the dorsal root ganglion (DRG). Ectopia originating in the DRG can summate with ectopia originating from neuromas in the stump. Indeed, processes such as cross-excitation can lead to the depolarization and activation of neighboring neurons, significantly amplifying the overall ectopic barrage (Devor, M., 2006). In experimental preparations and in humans it was found that anesthetic block of neuromas eliminates spontaneous and stimulation-induced nerve activity related to the stump, but not ectopic activity potentially originating in the DRG (Nystrom, B. and Hagbarth, K. E., 1981). Interestingly, there is evidence for genetic factors in the predisposition to develop ectopic neuroma, DRG discharge, and neuropathic pain. For example, Devor M. *et al.* (2005) presented evidence for the presence of several genes that predisposes to the pain behavior that follows peripheral neurectomy in rodents. This neuroma model of neuropathic pain has been considered to be a valid animal surrogate of phantom limb pain in humans.

Elevated sympathetic discharge, as well as increased levels of circulating epinephrine, can trigger and exacerbate ectopic neuronal activity from neuromas (Devor, M., 2006). In addition to such sympathetic–sensory coupling at the level of the neuroma, sympathetic–sensory coupling also occurs at the level of the DRG. This may account for the frequent exacerbation of phantom pain at times of emotional distress. Additional factors such as temperature, oxygenation level, and local inflammation

in neuromas and associated DRGs may also play a role. The sympathetic maintenance of phantom limb pain in some patients is supported by evidence that systemic adrenergic blocking agents, and targeted chemical or surgical blockade of sympathetic nerves and ganglia, sometimes reduce phantom limb pain. Likewise, injections of epinephrine into stump neuromas have been shown to increase phantom limb pain and paresthesias in some amputees. Although sympathetically maintained pain does not necessarily covary with regional sympathetic abnormalities, in some patients, sympathetic dysregulation in the residual limb is apparent. Reduced near-surface blood flow to a limb has been implicated as a predictive physiological correlate of burning phantom limb pain. Correspondingly, onset and intensity of cramping and squeezing descriptions of phantom pain have been related to muscle tension in the residual limb. This relationship seems not to hold for any other descriptors of phantom pain. In addition, lower skin temperature in the residual limb in amputees with phantom limb pain and phantom sensation and a close relationship between phantom limb sensation and skin conductance responses in the residual limb can be viewed as evidence of a sympathetic-efferent somatic-afferent mechanism (for review see Sherman, R. A., 1997).

5.46.3 Central Factors

5.46.3.1 The Spinal Cord

Anecdotal evidence in human amputees first suggested that spinal mechanisms may play a role in phantom limb pain. For example, during spinal anesthesia, phantom pains have been reported to reoccur in patients who were pain-free at the time of the procedure. Experimental data in human amputees are lacking, but increasing amounts of evidence based on animal models of nerve injury are becoming available.

Increased activity in peripheral nociceptors leads to an enduring change in the synaptic responsiveness of neurons in the dorsal horn of the spinal cord, a process called central sensitization (Woolf, C. J. and Salter, M., 2006). Central sensitization is also triggered by nerve injury such as occurs during amputation. For example, spinal changes associated with nerve injury include increased firing of the dorsal horn neurons, structural changes at the central endings of the primary sensory neurons, and reduced inhibitory processes. Inhibitory GABAergic and glycinergic interneurons in the spinal cord may actually be destroyed by rapid ectopic discharge or other effects of axotomy, contributing to a hyperexcitable spinal cord (Scholz, J. and Woolf, C., 2006). Changes have also been noted in ascending projection neurons. The cascade of biological events that take place in the spinal cord after peripheral nerve damage may trigger abnormal firing of spinal origin. Part of this sensitization is due to facilitation of the response of *N*-methyl-D-aspartic acid (NMDA) receptors to the primary afferent neurotransmitter glutamate (Sandkühler, J., 2000). A remarkable effect of the spinal changes evoked by nerve injury is that low-threshold afferents may become functionally connected to ascending spinal projection neurons that carry nociceptive information. When this happens, normally innocuous A-fiber input from the periphery, ectopic input as well as input from residual intact low-threshold afferents, may contribute to phantom pain sensation.

A number of additional central nervous system (CNS) processes are thought to contribute to the hyperexcitability of spinal cord circuitry following major nerve damage. For example, there may be downregulation of opioid receptors, both on primary afferent endings and on intrinsic spinal neurons. This is expected to add to disinhibition due to the reduction of GABA and glycine activity. In addition, cholycystokinin, an endogenous inhibitor of the opiate receptor, is upregulated in injured tissue (for review see Woolf, C. J. and Salter, M., 2006). Another interesting example of changed gene expression after axotomy is the appearance of the neuropeptide substance P in low-threshold Aβ neurons. Substance P is normally expressed only by Aδ and C afferents, most of which are nociceptors. The injury-triggered expression of substance P by Aβ fibers may render them more like nociceptors. For example, it may permit ectopic or normal activity in Aβ fibers to trigger and maintain central sensitization. Changes such as these in gene expression in injured afferents (and in some postsynaptic spinal neurons), which result in a change in their functioning (i.e., their phenotype), are referred to as phenotypic switch. Recent work based on gene chip technology indicates that hundreds of genes are up- or downregulated in DRG and spinal neurons following peripheral nerve injury.

Following peripheral nerve injury, degeneration of central projection axon occurs. Massive deafferentation is observed when dorsal roots are injured, or avulsed from the spinal cord. Deafferentation may act

hand-in-hand with the central effects of peripheral denervation to bring about the changes that contribute to spinal hyperexcitability. A mechanism that may be of special relevance to phantom phenomena is the invasion of regions of the spinal cord functionally vacated from injured afferents. For example, in the neuroma model in rats and cats, there is an expansion of receptive fields on skin adjacent to the denervated part of the limb, and a shift of activity from these adjacent areas into regions of the spinal cord that previously served the part of the limb that was functionally deafferented by the nerve lesion (Devor, M. and Wall, P. D., 1978). Such reorganization of the spinal map of the limb, which is probably due to unmasking of previously silent connections, is reflected in brainstem and cortical remapping also.

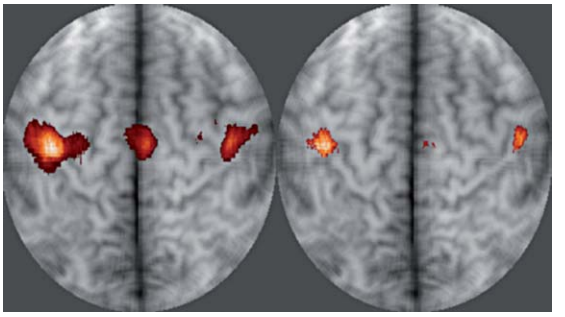

Figure 1 The representation of lip movements in amputees with phantom limb pain (left) and without phantom limb pain (right) in primary somatosensory cortex based on functional magnetic resonance imaging. Note that the amputees with phantom limb pain activate both the cortical hand and the mouth representation whereas the amputees without phantom limb pain activate only the cortical mouth representation.

5.46.3.2 Supraspinal Changes

Supraspinal changes related to phantom limb pain involve the brain stem, the thalamus, and the cerebral cortex (for review see Flor, H. *et al.*, 2006). New insights into phantom limb pain have come from studies demonstrating changes in the functional and structural architecture of primary somatosensory cortex subsequent to amputation and deafferentation in adult monkeys. In these studies, the amputation of digits in an adult owl monkey led to an invasion of adjacent areas into the representation zone of the deafferented fingers. Several imaging studies (for review see Flor, H., 2002) have reported that upper extremity amputees actually show a shift of the mouth into the hand representation in primary somatosensory and motor cortex (Figure 1). Flor H. *et al.* (1995) provided evidence that these cortical changes are less related to referred sensations but rather have a close association with phantom limb pain. The larger the shift of the mouth representation into the zone that formerly represented the amputated hand and arm the larger the phantom limb pain. These cortical changes could be reversed by the elimination of peripheral input from the amputation stump using brachial plexus anesthesia. Peripheral anesthesia completely eliminated cortical reorganization and phantom limb pain in half of the amputees that were studied. In the remaining half, both cortical reorganization and phantom limb pain remained unchanged (Birbaumer, N. *et al.*, 1997). This result suggests that in some amputees, cortical reorganization and phantom limb pain may be maintained by peripheral input whereas in others central, potentially intracortical changes might be more important.

It is so far not known to what extent spinal changes contribute to these supraspinal alterations. It was shown that axonal sprouting in the cortex underlies the reorganizational changes observed in amputated monkeys (Florence, S. L. *et al.*, 1998). Thalamic stimulation and recordings in human amputees have revealed that reorganizational changes may also occur at the thalamic level and are closely related to the perception of phantom limbs and phantom limb pain (Davis, K. D. *et al.*, 1998). Studies in animals have shown that these changes may be relayed from the spinal and brain stem level; however, changes on the subcortical levels may also originate in the cortex, which has strong efferent connections to the thalamus and lower structures.

Sometimes pain in the phantom is similar to the pain that existed in the limb prior to amputation. The likelihood of this ranges from 10% to 79% in different reports and depends on the type and time of assessment (see Katz, J. and Melzack, R., 1990). The type and time of assessment and potential errors in retrospective reports are important determinants of the incidence of these pain memories. It has been proposed that pain memories established prior to the amputation are powerful elicitors of phantom limb pain (Katz, J. and Melzack, R., 1990; Flor, H., 2002). Pain memories may be implicit and not readily accessible to conscious recollection. The term implicit pain memory refers to central changes related to nociceptive input that lead to subsequent altered processing of the somatosensory system and do not require changes

in conscious processing of the pain experience (Flor, H., 2002). In patients with chronic back pain it was shown that increasing chronicity is correlated with an increase in the representation zone of the back in primary somatosensory cortex, and it was also reported that the experience of acute pain alters the map in primary somatosensory cortex. These data suggest that long-lasting noxious input may lead to long-term changes at the central and especially at the cortical level. It has long been known that the primary somatosensory cortex is involved in the processing of pain and that it may be important for the sensory-discriminative aspects of the pain experience. There have also been reports that phantom limb pain was abolished after the surgical removal of portions of the primary somatosensory cortex and that stimulation of somatosensory cortex evoked phantom limb pain. If a somatosensory pain memory has been established with an important neural correlate in spinal and supraspinal structures, such as in primary somatosensory cortex, subsequent deafferentation and an invasion of the amputation zone by neighboring input may preferentially activate cortical neurons coding for pain. Since the cortical area coding input from the periphery seems to stay assigned to the original zone of input, the activation in the cortical zone representing the amputated limb is referred to this limb and the activation is interpreted as phantom sensation and phantom limb pain. It is likely that not only the areas involved in sensory-discriminative aspects of pain reorganize but also that those areas that mediate affective–motivational aspects of pain such as the insula and the anterior cingulate cortex undergo plastic changes that contribute to the experience of phantom pain. A prospective study (Larbig *et al.,* unpublished data) showed that the best predictor of phantom limb pain 12 months after an amputation is chronic pain before the amputation thus supporting the pain memory hypothesis. However, these authors tested a sample that did not include traumatic amputees but mainly amputees with long-standing prior pain problems. Further research is needed to better clarify these relationships.

5.46.4 Implications for the Treatment and Prevention of Phantom Limb Pain

Several studies, including large surveys of amputees, have shown that most treatments for phantom limb pain are ineffective and fail to consider the mechanisms underlying the production of the pain (Sindrup, S. H. and Jensen, T. S., 1999). Most studies are uncontrolled short-term assessments of small samples of phantom limb pain patients. The maximum benefit reported from a host of treatments such as local anesthesia, sympathectomy, dorsal root entry zone lesions, cordotomy and rhizotomy, neurostimulation methods, or pharmacological interventions such as anticonvulsants, barbiturates, antidepressants, neuroleptics, and muscle relaxants seems to be around 30%. This does not exceed the placebo effect reported in other studies. Controlled studies have been performed for opioids, calcitonin, ketamine, dextromethorphan, and gabapentin (see Nikolajsen, L. and Jensen, T. S., 2006), all of which were found to effectively reduce phantom limb pain. Mechanism-based treatments are rare but have been shown to be effective in a few small but mostly uncontrolled studies. Lidocaine was found to reduce phantom limb pain of patients with neuromas in two small-sample controlled studies. Biofeedback treatments resulting in vasodilatation of the residual limb or decreased muscle tension in the residual limb help to reduce phantom limb pain and seem promising in patients where peripheral factors contribute to the pain (Flor, H., 2002).

Based on the findings from neuroelectric and neuromagnetic source imaging, changes in cortical reorganization might influence phantom limb pain. Animal work on stimulation-induced plasticity would suggest that extensive behaviorally relevant stimulation of a body part leads to the expansion of its representation zone. It was shown that intensive use of a myoelectric prosthesis was positively correlated with both reduced phantom limb pain and reduced cortical reorganization. When cortical reorganization was partialled out, the relationship between prosthesis use and reduced phantom limb pain was no longer significant suggesting that cortical reorganization mediates this relationship. An alternative approach in patients where prosthesis use is not viable is the application of behaviorally relevant stimulation. A 2-week training that consisted of a discrimination training of electric stimuli to the stump for 2 h per day led to significant improvements in phantom limb pain and a significant reversal of cortical reorganization (Flor, H. *et al.*, 2001). A control group of patients who received standard medical treatment and general psychological counseling in this time period did not show similar changes in cortical reorganization and phantom limb pain. The basic idea of the

treatment was to provide input into the amputation zone and thus undo the reorganizational changes that occurred subsequent to the amputation. Mirror treatment (where a mirror is used to trick the brain into perceiving movement of the phantom when the intact limb is moved) might be effective but has so far only been tested in an anecdotal manner.

Preemptive analgesia refers to the attempt to prevent chronic pain by early intervention before acute pain occurs, for example, before and during surgery. Based on the data on sensitization of spinal neurons by afferent barrage it has been suggested that general anesthesia should be complemented by peripheral anesthesia thus preventing peripheral nociceptive input from reaching the spinal cord and higher centers. However, preemptive analgesia that included both general and spinal anesthesia has not consistently been efficacious in preventing the onset of phantom limb pain (for review see Nikolajsen, L. and Jensen, T. S., 2006). A preexisting pain memory that has already led to central and especially cortical changes would not necessarily be affected by a short-term elimination of afferent barrage. Thus, it is possible that peripheral analgesia would eliminate new but not preexisting central changes in the perioperative phase. In addition, a short-term blockade is not sufficient to prevent discharges from severed peripheral nerves to reach the CNS. The perioperative use of NMDA receptor antagonists or GABA agonists might therefore be useful.

5.46.5 Future Developments

Both peripheral and central factors and their interaction need to be examined more closely in animal models of amputation-related pain and in human amputees. The role of spinal mechanisms has so far not been sufficiently elucidated. The detection of genes relevant for the development of phantom pain-like behaviors in animal is an important step and may aid in the identification of predisposing factors for phantom limb pain as well as in the development of new interventions. The development of more powerful treatments for phantom limb pain needs controlled treatment outcome, prospective and double-blind placebo-controlled outcome research. Only then effective evidence-based interventions will be available.

Glossary

cytoarchitectony (cytoarchitectonic) Anatomical method based on microscopic observation of brain slices used to delineate cortical areas according to the organization of the different types of gray matter cells (neurons). This technique permits the drawing of cytoarchitectonic maps of the cortex, of which the most widely used is that of Korbinian Brodmann, first described in 1909, which counts 52 distinct areas in the human brain. The thickness of two different types of cortical cells layers (granule and pyramidal cells) and the number of layers are the two main parameters used for cytoarchitectonic mapping. Granule cells are over-represented in primary sensory (visual, auditory, and somatosensory) cortical areas (granular cortex), while large pyramidal cells are characteristic of the primary motor cortex (agranular cortex).

deep-brain stimulation Technique involving stimulating the brain with electric current pulses of low intensity using depth electrodes implanted through the skull. In humans, this technique can be used for therapeutic or diagnostic purposes. High-frequency continuous (or chronic) deep-brain stimulation is used as a treatment in various neurological diseases, e.g., Parkinson's disease. For diagnosis purposes, single pulses or trains of pulses are used mostly in presurgical assessment

of patients with drug-resistant focal epileptic seizures in order to map the seizure focus (or epileptogenic zone) and the functional areas surrounding the focus. Chronically implanted electrodes are painless; they also permit the recording of ongoing brain activity and evoked potentials.

discharge (epileptic discharge, after-discharge) Abnormal electroencephalographic (EEG) activity with abrupt onset and termination lasting at least several seconds seen during an epileptic seizure; discharges can be recorded either by scalp or by depth electrodes. They can occur spontaneously or be triggered by deep-brain stimulation and then named after-discharges.

electroencephalography (EEG) The record of electrical activity of the brain taken by means of electrodes placed on the surface of the scalp. First applied to study the activity of the human brain by Hans Berger in 1924, this noninvasive technique is still used routinely for the diagnosis of epilepsy.

evoked potentials (EPs) Brain electric response (wave or complex of waves) elicited by and time-locked to a physiological or nonphysiological stimulus, the timing of which can be reliably assessed, e.g., a short duration. Laser beam applied to the skin surface. Because of their low voltage most of EPs are not evident from the ongoing electroencephalographic (EEG) activity after a single stimulation. Repeated stimulations and computer summation techniques are thus needed for their detection. The number of single responses to be summated is a function of the signal-to-noise ratio (ratio between the EP and ongoing EEG activity voltages); this number is higher for scalp than for depth intracerebral recordings.

somatotopy (somatotopic) Representation maps of peripheral skin areas and joints in the somatosensory cortex that were first described in the human brain by Wilder Penfield using electric stimulation of parietal cortex. The even existence of such maps demonstrates that granule cells receiving inputs from the same peripheral areas are grouped together in the somatosensory cortex. Microelectrode recordings in mammalian brain including monkeys have shown that separate somatotopic maps of the peripheral skin and joint receptors can be drawn in the somatosensory cortical areas.

somatosensory areas (S1, S2) Cortical areas containing a full somatotopic map of the contralateral body half that have been identified in mammals and human brain by means of electric cortical stimulation, evoked potentials, brain imaging (functional magnetic resonance imaging), and unit or multiple cell responses. The human primary sensory area (S1) is located in the postcentral parietal gyrus and the second somatosensory area (S2) is located in the upper bank of the sylvian fissure (parietal operculum).

stereotaxy (stereotactic) The stereotactic space first described by Jean Talairach is a three-dimensional representation of the human brain in which each point in the brain can be located according to its coordinates (*x*, *y*, and *z*) in a Cartesian space. The space is defined by the intersection of the mid-sagittal plane and the plane perpendicular to mid-sagittal plane passing through the anterior and posterior commissure of the brain (AC–PC). Using depth electrodes implanted perpendicular to the mid-sagittal plane, any given recording or stimulation site can be localized by its stereotactic coordinates.

5.47.1 Anatomy, Connections, and Physiology of the Insula in Primates

5.47.1.1 The Insula as the Fifth Lobe of the Brain

In an article published in 1896 that was devoted to the comparative anatomy of the insula Clark T. E. (1896) quoted 39 synonyms used in anatomical literature to name the fifth lobe of the brain buried in the lateral sulcus and covered by the opercular parts of the frontal, parietal, and temporal lobes, among which the term insula, first proposed by Reil in 1804, has prevailed. Due to its anatomical situation in depth of brain lateral fissure (see Figure 1 and Tanriover, N. *et al.*, 2004), and its cytoarchitectonic organization the insula has long be considered by anatomists as a rather isolated lobe of the brain mostly devoted to the processing of body and visceral sensation including gustation, pain, and other emotions, as well as to visceromotor and autonomic control. In primates including humans, the insula shows a caudorostral sequence of three distinct cytoarchitectonic areas namely; (1) a large area of granular cortex, at its upper and posterior part, whose structure is very similar to that of the second

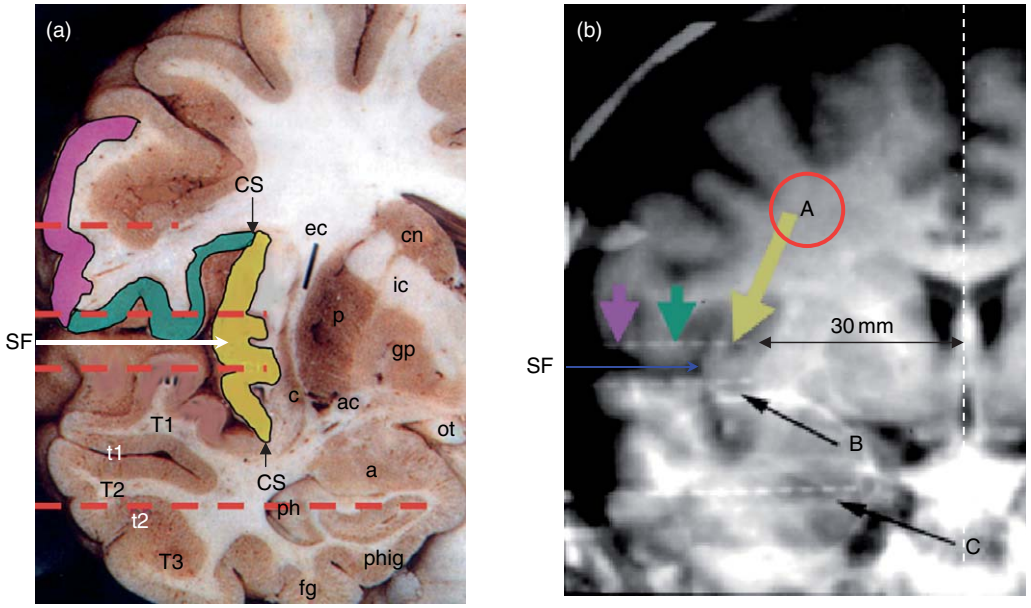

Figure 1 Anatomy of the human insular lobe (frontal slices). A) Anatomical fontal brain section showing the deep location of the insula (in yellow) in the sylvian fissure (SF, white arrow), which separates the frontal and parietal lobes (above) from the temporal lobe (below). The second somatosensory area (S2 in green), which occupies the superior bank of the SF, has common borders with the lower part of the primary somatosensory area (S1 in purple), and the insula. The circular sulcus (CS) separates the insula from the parietal operculum S2 and the first temporal gyrus (T1). The dashed red lines indicates the trajectory of depth electrodes used for insular, parietal, and temporal lobes recordings in patients with epilepsy of the temporal lobe and perisylvian cortex (see Isnard, J. *et al*., 2004). See also Figure 4 for sagittal view of the insula. B) Magnetic resonance imaging (MRI) slice showing the projection of the recording electrodes implanted horizontally perpendicular to the midline sagittal plane (dashed vertical white line). Recording contacts appears as small white segments along the electrodes trajectory. The deepest contacts of electrodes A and B are located in the insular cortex. The depths coordinates (x) of each contact is calculated from the midline sagittal plane in the human brain stereotactic space of Talairach. The x coordinates of insular recording sites vary from 27 mm to 36 mm from midline. Electrode A (red circle) contacts explore from depth to surface: the insula (yellow arrow), the S2 area (green arrow; $38 < x < 46$ mm) and the lower part of the S1 area (purple arrow; $48 < x < 63$ mm). Electrode B contacts explore the insula and the first temporal gyrus (T1 in Figure 1A). Electrode C contacts explore the second temporal gyrus (T2 in Figure 1B) and hippocampus. a, amygdala; ac, anterior commissure; c, claustrum; CS, circular sulcus; cn, caudate nucleus; ec, external capsule; fg, fusiform grus; gp, globus pallidus; ic, internal capsule; ot, optic tract; phig, parahippocamplal gyrus; SF, sylvian fissure; T1, first temporal gyrus; t1, first temporal sulcus; T2, second temporal gyrus; t2, second temporal sulcus; T3, third temporal gyrus.

somatosensory (S2) cortical area, which is involved mostly in the processing of somatosensory and pain sensation; (2) a transitional dysgranular field localized in its anterosuperior part involved in gustation and visceral sensation; and (3) an anteroventral agranular field, which is in continuity with the temporal pole and olfactory proisocortex, and related to olfactory and autonomic functions (see Tanriover, N. *et al*., 2004 for a review).

5.47.1.2 The Insula as a Node in a Distributed Cortical Network

The insula is characterized by anatomical borders that are defined by a limiting sulcus (the circuminsular fissure) but also by fuzzy cytoarchitectonic borders with neighboring cortical areas and by a dense network of corticocortical connections with adjacent or more distant cortical areas. Therefore its function cannot be sketched as an isolated functional center, as suggested by the term insula. A complete description of insular connections is given in the review by Augustine J. R. (1996) showing that the insula is connected to the limbic areas, amygdalar nucleus, basal ganglia, and all of the cortical lobes, except the occipital lobe. Several attempts have been made to identify functional networks in which the insula could play the role of a functional node. Among these networks the perisylvian–insular, the temporo–limbic–insular and the mesial–orbitofrontal–insular

networks (Mesulam, M. M. and Mufson, E. J., 1982) deserve the attention of pain physiologists because they are involved in pain localization and intensity encoding, as well as in emotional and behavioral reaction to pain.

5.47.1.3 The Insula as a Polymodal Area

The question of insular physiology has been addressed by studies using neuroimaging, evoked potentials (EPs), and direct stimulation in humans as well microelectrode studies in monkeys (Augustine, J. R., 1996). These studies have confirmed that the insula is involved in somatosensory and pain sensation as assessed by numerous functional imaging studies in humans (see Peyron, R. *et al.*, 2002 for a review), as well as by the somatosensory and pain-evoked response recordings and direct electric stimulations of the insular cortex that are detailed below in this chapter. However, the insula also proved to be a highly organized lobe with multiple specific functions other than pain including in particular:

Visceral sensation, visceromotor control.

Cardiovascular function as demonstrated by insular stimulation in epileptic patients that produces changes in heart rate or blood pressure in 50% of cases (Oppenheimer, S. M. *et al.*, 1992), thus leading to suspect a role of insular discharges in cardiac arrhythmias causing sudden death during epileptic seizures.

Gustation as assessed first by the stimulation studies of Penfield W. and Faulk M. E. (1955) and further confirmed by neuroimaging studies and microelectrode recordings of insular neurons in monkeys. These physiological findings are consistent with the altered taste perception observed in patients with insular lesions.

Audition and language, in particular allocation of auditory attention, tuning in to novel auditory stimuli, temporal, and phonological processing of auditory stimuli. Furthermore several studies suggest that both right and left insulas are involved in the control of speech production.

5.47.1.4 The Insula as Part of the Mirror-Neuron System

Some recent studies suggest that the insular lobe could belong to the mirror-neuron system that characterizes regions of the brain that are able to respond when the subject performs an action and when the subject observes another individual doing a similar action (see Rizzolatti, G. and Craighero, L., 2004 for a review). The concept also refers to regions of the brain that are able to encode for a sensation (or emotion) perceived by the subject and to respond to the observation of others experiencing that sensation (or emotion). In the human insula, the regions involved in visceral sensation or visceromotor responses are also responding to faces expressing disgust (Krolak-Salmon, P. *et al.*, 2003). Similarly the human insula respond to both pain perception and empathy for others' pain (Jackson, P. L. *et al.*, 2005).

5.47.2 Rational, Ethical Limitations and Procedure of Insular Recording and Stimulations in Humans

5.47.2.1 Recording and Stimulation of the Human Insula Are Justified only in the Context of Presurgical Evaluation of Epilepsy

In humans, electrical stimulation of the cortex, as well as invasive intracranial recordings of the cerebral activity, including surface recordings using electrodes placed on the cortex (electrocorticography) and depth recordings using electrodes implanted directly in the cortex (stereotactic electroencephalography or SEEG), aims at localizing the area that produces focal epileptic seizures. This area, referred to as the epileptogenic zone (EZ; Rosenow, F. and Luders, H. O., 2001), is that which is surgically removed to obtain seizure freedom in patients whose epilepsy cannot be controlled by conventional drug treatment. Ethically such recordings are justified only when the EZ cannot be localized noninvasively either by scalp recordings or neuroimaging techniques. In this context, invasive explorations aim mostly at recording spontaneous seizures. They are also used to perform a functional mapping of the cortex located in, or in the vicinity of, the EZ, in order to predict the functional consequences of the surgical treatment, which consists of removing the EZ cortex. This procedure, named cortectomy, is possible provided that the EZ is not located in an eloquent area involved in essential cortical functions such as language, memory, motor control, and vision. Both the recording of responses evoked by sensory stimulations and direct electrical stimulation of the cortex are commonly used to achieve this functional mapping in epilepsy surgery centers around the world. This context obviously entails some limitations in the use of depth cortical

recordings and stimulation in studies of human brain physiology.

5.47.2.2 Depth Intracortical Electrodes Are Needed to Explore the Insula

Due to its deep location in the lateral fissure the insula can be explored either by electrocorticography during surgery in patients whose frontoparietal or temporal operculum has been removed by a previous cortectomy, as was the case in the few patients first explored in Montreal by Penfield W. and Faulk M. E. (1955), or by depth SEEG electrodes implanted perpendicular to the mid-sagittal plane through the opercular cortex (Figure 1). These electrodes usually have five to ten contacts, each of 2 mm in length separated by 1.5 mm and can be left in place chronically up to 15 days (Isnard, J. *et al.*, 2000; 2004). Only the deepest contacts of such electrodes reach the insular cortex while the superficial ones explore the frontoparietal or temporal opercular cortex. Therefore, concerning somatosensory responsive areas located close to the lateral fissure, it must be checked on individual brain magnetic resonance imaging (MRI) whether contacts are located in the suprasylvian external parietal cortex (area S1), in the parietal operculum cortex (area S2), or in the insula. Oblique electrodes trajectories can also been used to explore the insula, thus increasing the number of contacts located in the insular cortex.

5.47.2.3 The Number of Electrodes Is Limited by Ethical Issues

Only the minimal number of electrodes that are useful to diagnosis can be implanted. Consequently the spatial resolution of the mapping in each individual is low, and pooling interindividual data is necessary to draw topographic functional maps of the human insula based on depth electrode data.

5.47.2.4 The Site of Electrode Implantation Is Guided by Diagnostic Purposes

Implantation sites are guided by the hypothesis issued from noninvasive investigations concerning the most probable EZ location. Furthermore the trajectory of electrode tracts is restricted by the anatomy of blood vessels that are particularly dense in the lateral fissure. Therefore, some parts of the insula are rarely or never explored.

5.47.2.5 Only Data Recorded in Nonepileptogenic Cortex are Physiologically Relevant

Data from cortical recordings or stimulations can be considered as reflecting the normal physiology of the brain on the condition that they have been obtained in cortical areas that are not involved in the epileptogenic process and do not show increased excitability to peripheral inputs or local electric fields produced by stimulation. Two criteria are commonly used to check this, which are first the absence of insular epileptic discharge in the insula during spontaneous seizures and, second, the absence of sustained afterdischarge after electrical stimulation of the insular cortex.

5.47.3 Insular Recordings of Pain Evoked Responses in Humans

In what follows we will describe responses to pain and nonpainful cutaneous stimuli because the same contact in the insula most often detects both types of responses. Moreover pain intensity rating is subjective and corresponds to various levels of stimulus intensity between subjects. In complement to insular responses we will also describe responses recorded in the second somatosensory (S2) area (Figure 1), which is located in the superior bank of the lateral fissure, because it has a blurred anatomical border with the granular insular cortex and is also involved in building up pain sensation.

5.47.3.1 The Laser Stimulus

Most of the studies on pain-EPs in normal subjects and patients use a laser beam (mostly CO_2) applied on the skin surface as a stimulus. The laser beam is known to stimulate the endings of small diameters fibers and mostly those of A delta fibers. When the power output is fixed, the amount of thermal energy delivered depends on the duration of the pulse, which is in the order of a few milliseconds and, thus, permits an accurate timing for the analysis of the electrophysiologic response. The energy density of the laser beam is expressed in milli-Joules per mm^2 of skin surface ($mJ\ mm^{-2}$). Threshold values for pain show large interindividual variations between 30 and 40 $mJ\ mm^{-2}$ using a CO_2 laser beam. In most studies, the sensation perceived by the subject is that of sharp pinprick, without poststimulus pain, considered as

characteristic of the sensations produced by the stimulation of A delta fibers. Although they are able to rate it on a visual analog scale of pain (usually at 4–7 on a 10 level scale), the subjects do not identify this sensation as a pain comparable to what they might have experienced in the past. Indeed no natural pain is provoked by selective activation of the A delta fibers, and this must be kept in mind when using laser stimulation in pain studies. In particular, the laser stimulus can be considered as adequate to assess the intensity coding of a pain stimulus, but is suboptimal for studying of the emotional reaction to pain.

5.47.3.2 Cortical Surface Recordings (Electrocorticography)

Lenz F. A. *et al.* (1998) were the first to record cortical surface recordings by means of a subdural grid of electrodes placed on the surface of the parietal operculum with CO_2-laser-evoked potentials (LEPs) peaking between 160 and 340 ms after the stimulus. The spatial distribution of this response over the cortical surface of the perisylvian cortex was considered as compatible with generators located in the parietal operculum and/or in the insular cortices. However subdural electrodes placed over the sylvian area do not allow direct recording neither in the deep aspect of the frontoparietal opercular cortex nor in the insula.

5.47.3.3 Intracortical S2 Recordings

In humans, LEPs at stimulus intensities below and above pain threshold are recorded in the suprasylvian opercular cortex corresponding to the human S2 area (Frot, M. *et al.*, 2001). These responses are not picked up in the other areas most often explored in presurgical assessment of epilepsy including the amygdala, hippocampus, and orbitofrontal cortex. They show a biphasic negative–positive waveform peaking at 137 ± 13 ms (N140) and 172 ± 11 ms (P170), respectively, after stimulation of opposite hand (Figure 2). Similar responses are equally recorded in the homologous cortex, ipsilateral to the painful stimulus with a delay of 10–17 ms. The LEP voltage in S2 shows a significant increase as soon as the stimulus intensity reaches the sensory threshold as well as between sensory and pain thresholds while it rapidly reaches a plateau for intensities above pain threshold (Frot, M. *et al.*, 2007; Figure 3).

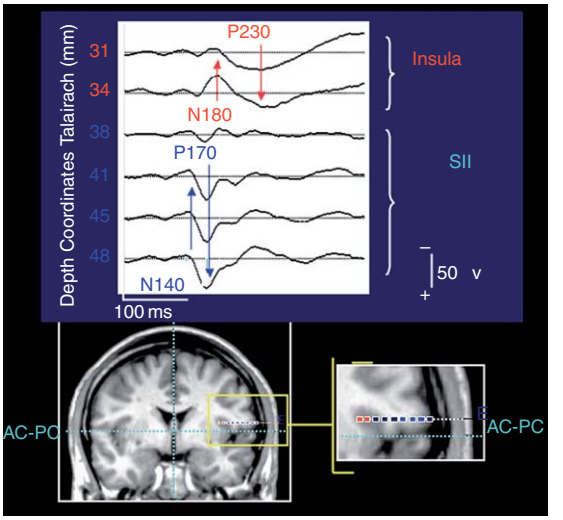

Figure 2 Pain laser-evoked potentials (LEPs) to skin laser stimulation of the dorsum of the hand. The lower part of the figure shows frontal magnetic resonance imaging slices of the right insula with projection of the contacts of a recording electrode exploring the insula (red) and S2 (blue). The vertical dashed blue line represent the midline sagittal plane, and the horizontal dashed blue line the anterior commissure–posterior commissure (AC–PC) horizontal plane used for stereotactic implantation of depth electrodes. Evoked potentials illustrated in the upper part of the figure are obtained by averaging responses to repeated stimulations of the left hand by a CO_2 laser beam. Figures along the vertical axis are the depth coordinates (x) in mm from midline of each recording contact. Note that distinct responses are obtained in both areas, which are separated by a delay of 50 ms.

5.47.3.4 Intracortical Insular Recordings

LEPs contralateral to stimulation recorded in the insular cortex itself (Frot, M. and Mauguière, F., 2003) consist in a N180 negative response (mean latency: 180 ± 16.5 ms) followed by a P230 positivity (mean latency: 226 ± 16 ms; Figure 2). As for S2, insular LEPs ipsilateral to stimulation peak 10–17 ms later than contralateral ones. LEP amplitudes increase between sensory and pain threshold intensities but, contrary to what is observed in S2, continue to increase significantly at intensities over the pain threshold (Figure 3).

The reason for the delay of ~ 50 ms (50 ± 16 ms between S2 N140 and insular N180 peaking latencies) observed between S2 and insular pain responses remains questionable. It is too long for a monosynaptic transmission from S2 to the insula, the two areas being interconnected through direct projections. Alternatively, knowing that both S2 and the insula

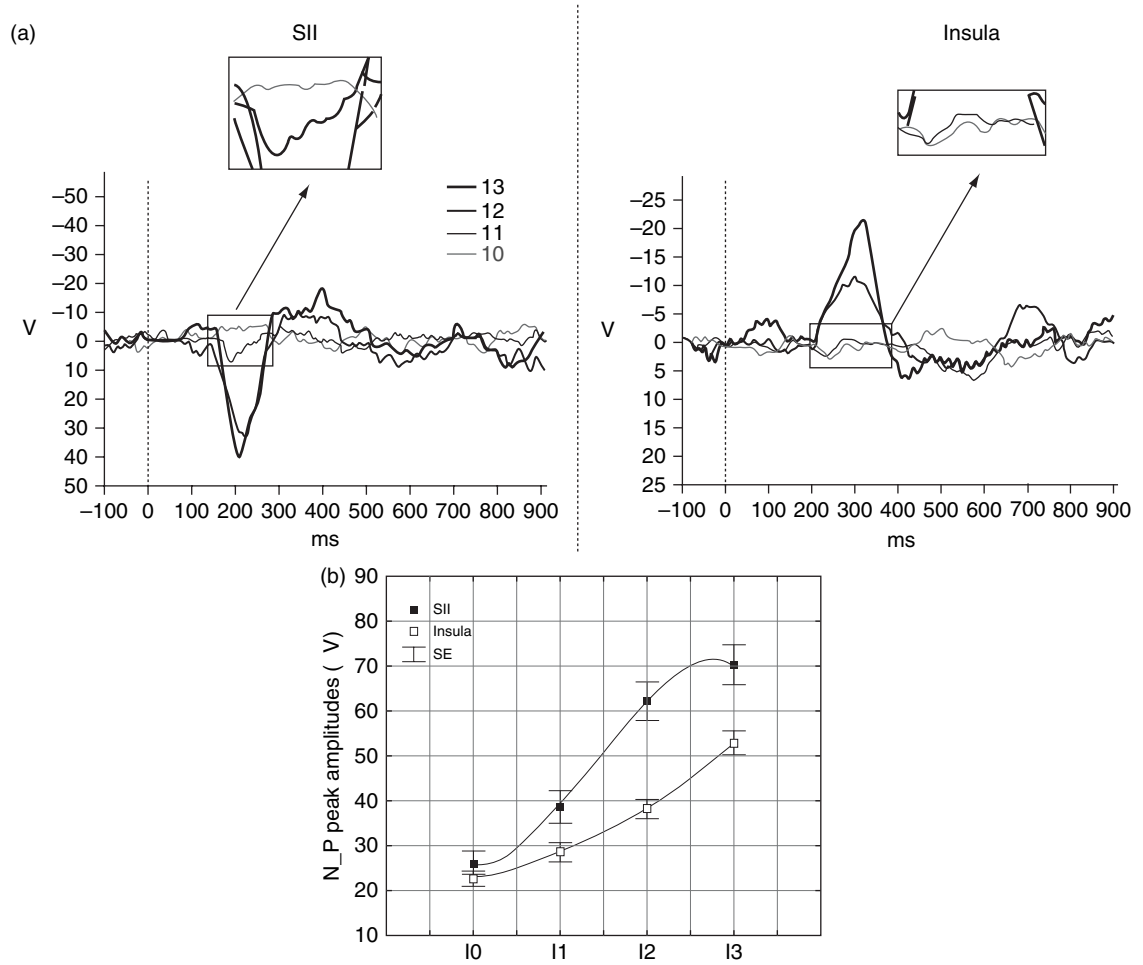

Figure 3 Effects of stimulus intensity on laser-evoked potential (LEP) amplitude in S2 and insula. A) LEP traces in S2 and insula to four different stimulus intensities are superimposed. CO_2 Laser pulses were applied at four different intensities in each subject. The power output being fixed, the amount of thermal energy delivered depends on the duration of the pulse. Pulse duration is set up according to subjects' subjective reports, rated on a visual analog scale (VAS) with an anchor point corresponding to the pain threshold. The printed scales consist of 10-cm horizontal lines where the left extreme is labeled no sensation and the right extreme maximal pain, and an anchored level 4 was at pain threshold (Lickert-type scale). The different stimuli and related subjective sensation are as follows: I0: below sensory threshold (pulse duration: 5–15 ms, mean energy density: 7 mJ mm^{-2}, no sensation); I1: above sensory threshold (pulse duration: 15–45 ms, mean energy density: 19 mJ mm^{-2}, producing a detectable nonpainful sensation reported for more than 90% of stimulations; For one-third of patients this sensation is a warmth sensation and for the others two-thirds a slight nonpainful pinprick sensation; VAS: 1.6 ± 1.09); I2: pain threshold (pulse duration: 25–80 ms, mean energy density: 33 mJ mm^{-2}, producing a pricking sensation, like a hair pulling or a drop of hot boiling water on the skin; VAS: 3.9 ± 1.46); I3: 20% above pain threshold (pulse duration: 35–110 ms, mean energy density: 46 mJ mm^{-2}, producing a pricking sensation described as clearly painful; VAS: 5.4 ± 1.6). In S2, a significant increase of the LEP is observed as soon as the stimulus intensity reaches the sensory threshold (between I0 and I1, $P < 0.001$), as well as between sensory and pain thresholds (I1 to I2, $P < 0.001$) while amplitudes rapidly reach a plateau for intensities above pain threshold (no significant amplitude difference between I2 and I3). In the insula, no significant amplitude increase is observed for low-stimulation intensities between I0 and I1, LEP amplitudes also increase between sensory and pain threshold intensities ($P < 0.05$ between I1 and I2) and continue to increase significantly at higher intensities over pain threshold ($P < 0.001$ between I2 and I3). B) Insula and S2 LEPs peaking amplitudes as a function of stimulus intensity. In these polynomial regression curves of the stimulus–response functions S2 LEPs amplitudes show a S-shaped profile with increasing stimulus intensities that reaches a plateau above pain threshold, while insular LEP amplitudes show an exponential profile. Laser stimuli above pain threshold trigger a maximal response in S2 and a pain level-related response in the insula (Modified from Frot, M., Magnin, M., Mauguière, F., and Garcia-Larrea, L. 2007. Human SII and posterior insula differently encode thermal laser stimuli. Cereb. Cortex 17, 610–620).

receive direct projections from the thalamus (see for a review Augustine, J. R., 1996) the explanation could be that the latter are triggered via thalamocortical fibers with a slower conduction than that of thalamic projections to the S2 area. To our knowledge, however, no electrophysiological demonstration of this hypothesis is hitherto available. A third hypothesis could be that the suprasylvian cortex and the insula are activated by inputs conveyed by peripheral fibers with different conduction velocities. Some studies have estimated the A delta conduction velocity in a large range of 7–20 m s^{-1} suggesting the existence of different A delta fiber subpopulations, with different conduction velocities. One can hypothesize that these different subpopulations of peripheral fibers could project in distinct cortical regions. However, to our knowledge, no electrophysiological study has been devoted to the identification of separate subpopulations of fibers with different conduction velocities in the spinothalamic tract or thalamocortical projections.

5.47.3.5 Topographic Specificity of Insular Laser-Evoked Potentials

Due to the anatomical proximity between the S2 area and the granular part of the insula the question arises whether insular responses might reflect the diffusion of S2 LEPs with a polarity reversal across the sylvian fissure, which is almost virtual in that region. The fact that when two contacts, or more, explore the insular cortex there is an amplitude increase from surface to depth of the N180–P230 response suggests that this is not so (see Frot, M. and Mauguière, F. 2003 for a complete discussion). However, the absolute proof that the N180–P230 is generated in the insular cortex would be its polarity reversal between the surface and the depth of the insular gray matter; unfortunately usual stereotactic recordings in patients do not have enough spatial resolution (2 mm interval between two neighboring contacts of 1.5 mm) to assess the distribution of potentials perpendicular to the cortical surface.

5.47.3.6 Interhemispheric Transmission of S2 and Insular Laser-Evoked Potentials

Insular and S2 responses to pain are bilateral; ipsilateral potentials peaking with a delay of 10–20 ms after contralateral ones. This delay is compatible with the interhemispheric transmission time through fibers of the corpus callosum as estimated by numerous studies (e.g., 15 ms between primary visual areas); it is in the same range as that measured between ipsi- and contralateral S2 magnetic fields evoked by electrical stimulation of the median nerve. The possibility remains, however, that responses ipsilateral to the stimulus could be triggered via ipsilateral thalamic fibers with slower conduction velocities. Only intracortical recordings of S2 or insular EPs to ipsilateral stimuli in patients with a lesion of the homologous areas in the opposite hemisphere could address this question directly.

5.47.4 Insular Stimulation

5.47.4.1 The Challenge of Insular Stimulation

In humans, it has long been a challenge to stimulate the insular cortex. Thus, only a few studies have reported nonnociceptive somesthetic symptoms, cardiovascular effects as well as visceromotor and viscerosensitive sensations consecutive to direct electrical stimulation of the insular cortex. Truly painful responses have not been reported during stimulation of any area of the cerebral cortex in humans by Penfield W. and Faulk M. E. (1955), who extensively stimulated the surface of all cortical areas of the human brain, including the insula, using surface electrodes. However, they did not explore the posterior part of the insula where electric stimulation evokes painful sensations.

Electric stimulations are produced by a current-regulated neurostimulator designed for a safe diagnostic stimulation of the human brain. Square pulses of current are applied between two adjacent contacts (bipolar stimulation) at a frequency of 50 Hz, pulse duration of 0.5 ms, train duration of 5 s, and intensity of 0.8–6.0 mA. These parameters are used to avoid any tissue injury (charge density per square pulse $<55\ \mu C\ cm^{-2}$; Gordon, B. *et al.*, 1990). This stimulation paradigm ensures a good spatial specificity with respect to the desired structures to be stimulated. The study of current densities in the cortex for bipolar stimulation with a 10-mA stimulating current shows that the peak current density occurs in the region immediately beneath the bipolar electrodes (0.05 A cm^{-2}) and declines rapidly to 0.02 A cm^{-2} 0.5 cm away, and that the current density decreases in relation to the square of the distance into the cortex. In S1, S2, and the insula, the minimal stimulation intensity necessary to elicit a clinical response is 1.6–1.9 mA (Mazzola, L. *et al.*, 2006). With these stimuli there is virtually no current spread out of the stimulation current dipole as defined by the distance of 5.5 mm

between the outer and inner limits of the superficial and deep-stimulating contacts, respectively (Ostrowsky, K. *et al*., 2002). Moreover it has been demonstrated that no significant cerebral blood flow change occurs at the site of cortical stimulation, or in its close vicinity, in the absence of epileptic after discharge.

5.47.4.2 Pain Evoked by Insular Stimulation

Painful sensations in response to direct electric stimulation of the insula have been reported by Ostrowsky K. *et al*. (2000; 2002) and more recently by Mazzola L. *et al*. (2006). Qualities of the evoked pain are described as burning, stinging, disabling sensation, or electrical shock. Pain intensity varies from mild to intolerable but is not related to stimulation intensity. Pain disappears as soon as the stimulation is interrupted in most cases except a few where an intense pain is followed by a sore feeling that can last up to 1 min after the end of the stimulation. It is located contralateral to the stimulation site or bilaterally when midline parts of the body are involved, and affects large areas of the body (e.g., face, upper limb, whole half of the body), suggesting that receptive fields for pain in the insular cortex are more extended that somatosensory fields in the SI and SII cortex (Mazzola, L. *et al*., 2006).

5.47.4.3 Anatomical Location of the Insular Pain Area

The area where pain can be elicited by direct electric stimulation occupies the posterosuperior part of the insular lobe (Figure 4). Surface electrodes cannot reach this area unless the lower precentral motor and postcentral somatosensory cortex be removed. This is the most probable reason why early electrocorticographic studies using that type of electrodes failed to produce pain by cortical stimulation in humans. Because only a few contacts can be placed in the insula of a given individual during stereotactic exploration of the brain with depth electrodes it is uncertain whether a pain somatopic representation of the body, comparable to that demonstrated in the primary somatosensory cortex (S1), does exist in the pain insular area. Moreover due to the large skin extent of pains evoked by insular stimulation that the somatotopic pain representation is likely to be much more fuzzy, with overlapping receptive fields, in the insular pain area than in S1 or S2 somatosensory areas.

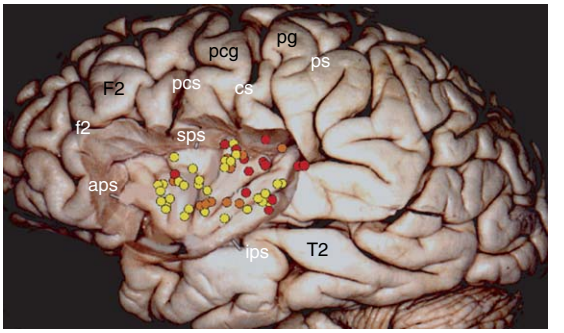

Figure 4 Pain insular area. The locations of stimulation sites in a population of patients are plotted on a sagittal view of the insula exposed by removal of the supra and infrasylvian cortex according to the type of somatosensory sensation reported by the subjects. Red dots: pain, Orange dots: nonpainful warm sensation, yellow dots: nonpainful paresthesias. Note that most of pain sensations are evoked by stimulation the posterior part of the insula situated behind the tip of the central sulcus (cs), while nonpainful responses are obtained over a larger and more anterior surface of the insular lobe. Aps, anterior peri-insular sulcus; cs, central sulcus; F2, second frontal gyrus; f2, second frontal sulcus; ips, inferior peri-insular sulcus; pcg, precentral gyrus; pg, postcentral gyrus; ps, parietal sulcus; sps, superior peri-insular sulcus; T2, second temporal gyrus.

Glossary

amygdala A group of neurons that is part of the limbic system. The amygdala is involved in many aspects of behavior such as memory, emotion, and motivation.

immunocytochemical staining A method that uses antibodies to identify and locate specific cellular components, such as neurotransmitters.

medial frontal, infralimbic, and cingulate cortices Different parts of the cerebral cortex that have been shown to be involved in different aspects of processing painful information.

nociception The perception of a stimulus that is potentially injurious to one's body.

nucleus accumbens A part of the limbic system involved in reward and addiction.

thalamus A part of the brain located at the center that processes sensory and motor information and sends the resulting information to the cerebral cortex.

5.48.1 What Is the Rostral Agranular Insular Cortex?

The rostral agranular insular cortex (RAIC) is a small area of the cerebral cortex located on the lateral aspect of the rat's cerebral hemisphere. The RAIC can be distinguished in terms of its location, cellular architecture, neurochemistry, and connectivity. Functionally, the RAIC is involved in processing pain information and, depending on which cells are activated, can act through connections with other brain areas to reduce or increase pain responses. The RAIC therefore is one of a limited number of cortical regions involved in the perception and response to pain.

5.48.2 Function of the Rostral Agranular Insular Cortex

Many parts of the cerebral cortex do not have precisely defined functions and usually do not have precisely defined borders. Until recently, the RAIC was one such region, but a picture indicating that the RAIC is involved in the behavioral responses to nociceptive (painful) stimuli is beginning to emerge from animal and human studies.

5.48.3 Anatomical Location

In the rat, the RAIC occupies a small area of the lateral aspect of cerebral cortex just above a groove,

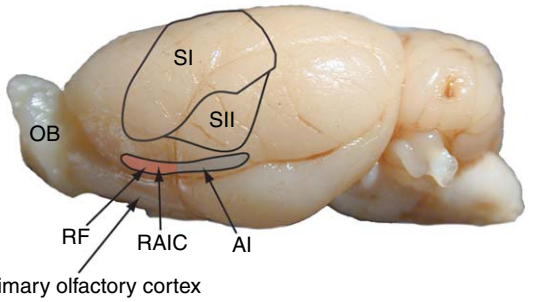

Figure 1 Lateral view of the rat brain. The rhinal fissure (RF) is seen as a prominent groove starting near the ventral anterior cortex and extending toward the posterior cortex. The agranular insular cortex is a thin strip of cortex lying just above (dorsal to) the RF and the rostral part (RAIC) is indicated in red. The approximate location of the primary somatosensory cortex (SI) and the secondary somatosensory cortex (SII) are indicated for reference. OB, olfactory bulb.

which is one of the few surface features of the rat cortex, called the rhinal fissure (Figure 1) (Paxinos, G., 1995). Agranular cortex is defined by the absence of a layer 4 that gives the cortex a less granular appearance than the adjacent areas. The region was described by Krettek J. E. and Price J. L. (1977) as a strip of agranular cortex located immediately above the rhinal fissure and bounded dorsally by granular cortex. Rostrally, the agranular cortex was further subdivided into a ventral and a dorsal agranular region. This description was later modified (Cechetto, D. F. and Saper, C. B., 1987) to include a dysgranular field between the agranular and granular cortices. The dysgranular field had a layer 4 that was intermediate in prominence between the fully developed layer 4 of the granular cortex and the absent layer 4 of the agranular cortex. Later studies all distinguish agranular, dysgranular, and granular fields although the precise boundaries, particularly between the dorsal agranular and dysgranular fields, were delineated differently.

5.48.4 Neurochemical Signature

Although classically cortical regions are defined by cytoarchitecture and location, modern neuroanatomical techniques have refined our understanding of cortical organization based on connections and neurochemical profile. The RAIC has been shown to be distinguished from surrounding regions by a distinct pattern of immunocytochemical staining (Figure 2) (Ohara, P. T. *et al.*, 2003). The first feature is a concentration of neurons in layer 5 of the RAIC that express the $GABA_B$ receptor (Jasmin, L. *et al.*, 2003), which is one of several types of receptors activated by the inhibitory neurotransmitter, gamma-aminobutyric acid (GABA). Similar concentrations of $GABA_B$ receptor-bearing neurons are also found in the insular cortex posterior to the RAIC and in a few other brain regions but are less concentrated in the remainder of the cortex. The neurons in layer 5 of the RAIC that express the $GABA_B$ receptor are large pyramidal projection neurons that have axons that leave the cortex and innervate other brain regions. This finding suggests that the neurons in the RAIC that have $GABA_B$ receptors play a specific role in how the RAIC communicates with other brain areas. A second notable feature of the RAIC is the concentration of nerve fibers containing the neurotransmitter dopamine. In the rat, there is only sparse dopamine innervation throughout most of the cortex dopamine fibers that are found in high concentration in then infralimbic cortex and in the RAIC (Figure 2). These dopamine fibers originate in a region of the brainstem called the ventral tegmental area (VTA) and probably are involved in determining the overall level of activity of the RAIC rather than conveying specific sensory information.

5.48.5 Connections of the Rostral Agranular Insular Cortex

The specific connections of a cortical region also help define the boundaries and give insight into the functions of the region. The RAIC shares the general pattern of connection common to most regions of cortex receiving its major subcortical afferents from the thalamus, having reciprocal connection with other cortical regions, and projecting to a number of subcortical sites (Jasmin, L. *et al.*, 2004). The picture that emerges from an analysis of the projections is that the RAIC plays a role in pain mechanisms. The inputs from the thalamus are from the nuclei that convey sensory information from the body. However, this input is not from thalamic nuclei that subserve the fine-detailed discriminative aspect of sensation (i.e., those that project to the primary somatosensory cortex), rather the input is from nuclei located in the midline of the thalamus that are generally associated with emotional or affective aspects of pain. The principal cortical connection of the RAIC is with areas such as the medial frontal, infralimbic, and cingulate cortices, which have long been known to

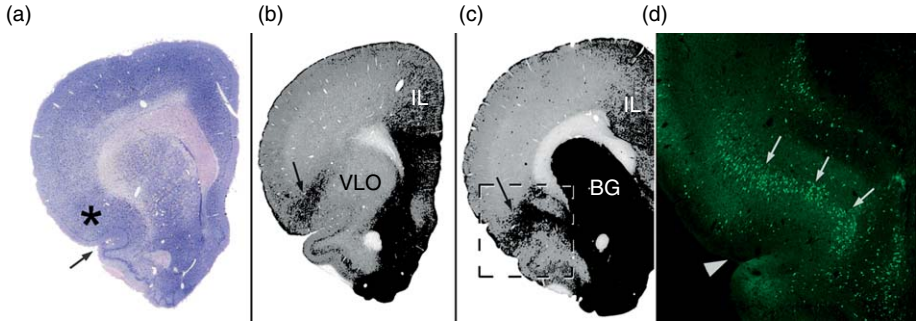

Figure 2 Coronal sections through the left anterior rat brain showing some of the characteristic features of the RAIC. (a) A section stained with a Nissl stain to show the general appearance and location of the RAIC. The rhinal fissure is indicated by the arrow and the asterisk indicates the location of the RAIC. (b, c) Sections stained immunocytochemically to show the location of fibers containing the neurotransmitter, dopamine. The contrast has been digitally enhanced to show the dopamine more clearly. The arrow indicates the region of dopamine staining that corresponds to the location of the RAIC. Intense staining is also present in the infralimbic cortex (IL), which is also a pain-related area, and in the basal ganglia (BG), which is a motor-related site. The ventrolateral orbital cortex (VLO), a site also associated with pain behavior, shows no dopamine staining. (d) A higher magnification of the boxed region indicated in (c). This section is stained to show the location of neurons that express the $GABA_B$ receptor (green-colored structures) in cortical layer 5. The arrowhead indicated the location of the rhinal fissure.

be associated with pain responses. The RAIC projects to a number of subcortical sites including the lateral hypothalamus, dorsal raphe, periaqueductal gray matter, pericerulear region, rostroventral medulla, and parabrachial nuclei – all of which play a role in pain inhibition mechanisms. Significant to the probable function of the RAIC are projections to the amygdala and the nucleus accumbens. These projections include a large component originating in the cells in layer 5 that express the $GABA_B$ receptor described above. The amygdala is known to be involved in several aspects of behavior including fear, anxiety, and attention (Williams, M. A. *et al.*, 2005).

5.48.6 Behavioral Studies

In addition to the connectional studies, there are a number of behavioral studies that give insight into the function of the RAIC. Direct injections of compounds into the RAIC have shown that morphine injection, increasing dopamine levels, and increasing GABA levels all result in behavioral antinociception. Because increasing GABA in the RAIC results in antinociception and the action of GABA is to inhibit neuronal activity, it suggests that activity in the RAIC is pronociceptive. Additional pharmacological experiments suggest that the neurons that express the $GABA_A$ and those that express the $GABA_B$ receptor change pain thresholds through different pathways. These antinociceptive effects mediated by cells that possess $GABA_A$ receptors occur through projections to the brainstem and activation of descending pain inhibitory systems. However, as noted above, the RAIC is characterized by an abundance of cells that have $GABA_B$ receptors. The changes in pain behavior mediated by the $GABA_B$ receptor-bearing neurons point to projections to the amygdala playing a key role. The proposal that the activity in the RAIC leads to increased pain was tested by inhibiting $GABA_A$ receptor-bearing neurons and at the same time activating $GABA_B$ receptor-bearing neurons. This experiment resulted in an increase in pain behavior (Jasmin, L. *et al.*, 2003). These studies highlight two important issues. First, changes in activity of the RAIC can result in both increases and decreases in pain response and the overall effect of the RAIC results from a balance of pro- and antinociceptive activity. Second, the RAIC probably changes pain behavior both by activating descending inhibitory circuits and by changing activity in the amygdala and other cortical area to change the emotional/affective response to painful stimuli.

5.48.7 Relationship with Adjacent Cortical Regions

The location and small size of the RAIC makes it difficult to unequivocally isolate it from surrounding regions. The agranular insular cortex has been most associated with visceral and gustatory responses, and

a number of studies on cells in the region have indicated that they respond to visceral input. These functions, however, seem more related to the more posterior regions of the agranular cortex or the dysgranular cortex immediately above the RAIC. Immediately anterior to the RAIC is the ventrolateral orbital cortex (VLO). This region of cortex in the rat is also associated with pain responses (Xie, Y. F. *et al.*, 2004). As with all parts of the cerebral cortex, it is often difficult to define a clear boundary between any two regions. For this, and other technical reasons such as diffusion of drugs when injected into a specific site, it is possible that some studies previously carried out on the VLO may have encroached upon the RAIC and vice versa. There are both similarities and differences between the VLO and the RAIC. Morphine injected into the VLO and RAIC both produce antinociception, but the application of drugs that inhibit GABA has no effect in the RAIC but do have antinociceptive effects in the VLO. There is less dopamine innervation of VLO, and although the VLO contains $GABA_B$ receptor-bearing cells, they are not as numerous as in the RAIC (Ohara, P. T. *et al.*, 2003). Whether the VLO and RAIC are really separate entities with specific, separate functions related to pain or whether both regions are parts of a larger forebrain nociceptive system is not clear.

5.48.8 Overview in the Rat

The major connections of the RAIC are with areas that have established roles in nociceptive information processing and behavior responses to nociceptive stimuli. RAIC projections to other cortical areas and subcortical sites such as the amygdala are likely to participate in the sensorimotor integration of nociceptive processing, while the hypothalamus and brainstem projections are most likely to contribute to descending pain inhibitory control.

5.48.9 From Rats to Humans

The agranular insular cortex is found in other mammals including cats, monkeys, and primates including humans (Augustine, J. R., 1996; Mesulam, M.-M., 2000). In primates, the divisions of the insular cortex are the same as in rats and the RAIC occupies an area immediately noticeable, that is, dorsal to the primary olfactory cortex.

The advent of high-resolution functional imaging has resulted in the availability of data relating to cortical function that has previously been difficult to obtain from animal studies (Figure 3). Specifically, it is possible to relate verbal descriptions and emotional responses to painful stimuli to specific cortical sites. In humans, imaging techniques and direct recording of field potentials show that painful stimuli activate the insular cortex (Coghill, R. C. *et al.*, 1994; Brooks, J. C. *et al.*, 2005). It has been possible to distinguish between activation of the anterior and of the posterior region of the agranular cortex located in the insular region (Strigo, I. A. *et al.*, 2003). The anterior insula, which might be considered most equivalent to the RAIC, is activated when a strong emotional response is associated with the nociceptive stimulus. The posterior insula and the adjacent parietal cortex, in turn, are activated by all nociceptive stimuli, independently of their emotional content. These differences in function between the anterior and the posterior insula are explained by their neural connectivity. Notably, ascending nociceptive afferents from the spinal cord and brainstem directly activate the posterior insula

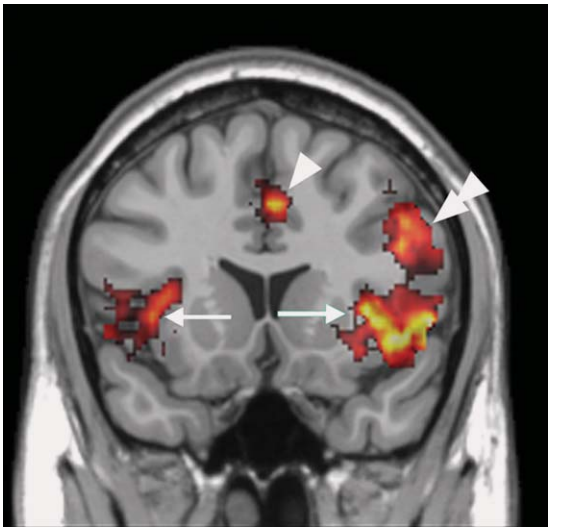

Figure 3 A functional magnetic resonance imaging blood oxygen level-dependent (fMRI BOLD) image averaged from nine normal healthy subjects who received a painful stimulus to the back. Note that the insular cortex is activated (arrows, red and yellow areas) on both sides of the cortex although more prominently on the left side. This bilateral activation of the insular region can be contrasted with the unilateral activation of other cortical regions such as the cingulate cortex (arrowhead) and dorsolateral prefrontal cortex (double arrowhead). Why the activation is lateralized in these latter areas in not known but is a common occurrence. Photo courtesy of Dr. Vania Apkarian, Northwestern University.

only. Accordingly, direct electrical stimulation of the posterior insula results in the generation of thermal sensations (Ostrowsky, K. *et al.*, 2002), and lesions of the posterior insula, and not the anterior insula, affect recognition of nociceptive heat (Greenspan, J. D. *et al.*, 1999). On the other hand, the anterior insula is implicated in the emotional awareness that occurs when a nociceptive stimuli endangers the self (Craig, A. D., 2002).

One aspect of function that has emerged from human studies and not fully explored in animal experiments is that in some cases activation of the anterior insula is lateralized. For example, air hunger activates mostly the right side (Banzett, R. B. *et al.*, 2000), and from this and other results, the right insular cortex has been assigned a greater role in the consciousness of the external world as well as interest in novelty (Manes, F. *et al.*, 1999). The left insula is more implicated in the regulation of cardiovascular function (Phillips, M. L. *et al.*, 2003).

5.48.10 Perspective

Our understating of cortical functioning, particularly with respect to pain, must be considered rudimentary. Although we refer to the RAIC as a distinct entity with a specific function in the rat, we need to remain aware of the close relationship it has with adjacent areas serving visceral functions and nearby regions such as the VLO involved in nociceptive processing. The most complete understanding of the RAIC will only come about when we understand how it is integrated into the other cortical and subcortical sites that appear to form a pain matrix. We also need to understand the relationship between the RAIC in the rat and the agranular insular cortex in the human. Although there are clear parallels between the two areas in terms of cytoarchitecture and function, it is not clear that they are strictly equivalent areas and our understanding of pain mechanisms in general will have to take into account such species-specific similarities and/or differences.

5.49.1 Introduction

Pain is a sensory process that reflects the level and intensity of noxious stimulus on one hand but is also closely controlled or modulated by the central nervous system (CNS). In fact, the intensity of the perceived pain is not necessarily proportional to the amount of stimulus under different conditions (Figure 1). Although psychological factors contribute to the variability of pain, the most important underlying mechanisms responsible for the variant pains are the existence of the endogenous pain modulatory systems, in which brainstem descending pathways play a fundamental role (Fields, H. L. and Basbaum, A. I., 1999; Millan, M. J., 2002). These pathways provide the neural mechanisms by which attentional, motivational, and cognitive variables filter ascending sensory information.

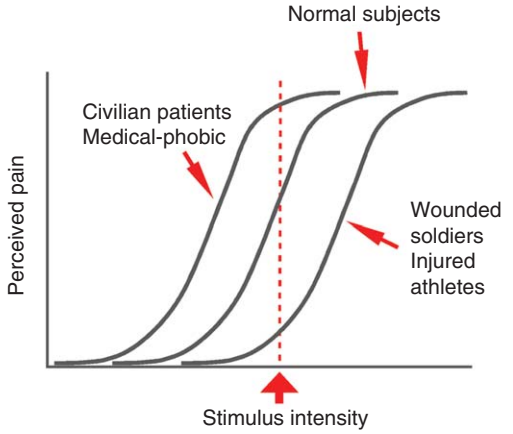

Figure 1 The variant pains. In this illustrative diagram, the intensity of the perceived pain is plotted against the stimulus intensity. The stimulus-response function curve of the normal subjects is located in the middle. For wounded soldiers and injured athletes, the curve may be shifted to the right and for civilian patients and medical-phobic, the curve may be shifted to the left. The shift of the curve is translated as changes in the sensation of pain. At certain stimulus intensity (arrow-dashed line), the civilian population may feel more pain and the wounded soldiers show less pain, when compared to the normal subjects. The endogenous pain modulatory system contributes to the variability of pain under different conditions. Adapted from Cervero, F. and Laird, J. M. 1996. Mechanisms of touch-evoked pain (allodynia): a new model. Pain 68, 13–23.

Our knowledge of the descending pain modulatory systems spans at least four decades. In 1965, Wall and Melzack in their gate control theory of pain questioned the concept of an invariant relationship between stimulus and sensation and a fixed, direct-line connection from the skin to the brain. They proposed that central signals arising from the brain could influence afferent input at the earliest synaptic levels of the somesthetic system, the spinal dorsal horn (Melzack, R. and Wall, P. D., 1965). Evidence supporting the concept was available even earlier when Hagbarth and colleagues (Hagbarth K. E. and Kerr, D. I., 1954; Hernandez-Peon, R. and Hagbarth, K. E., 1955) showed that sensory transmission through spinal cord and trigeminal sensory nuclei was influenced by descending fibers from the cerebral cortex. The gate control hypothesis placed this evidence within the framework of a theory of how pain modulation could account, in part, for the variant relationship between noxious stimuli and the sensations they produced. The first evidence to support endogenous pain control came from the study of Reynolds (Reynolds, D. V., 1969) who demonstrated that focal brain stimulation of the midbrain periaqueductal gray (PAG) produced sufficient analgesia to allow surgery in rats without the use of chemical anesthetics. Liebeskind and colleagues quickly confirmed this finding and concluded that stimulation of the PAG activated a normal function of the brain: pain inhibition (Mayer, D. J. *et al.*, 1971; Mayer, D. J. and Liebeskind, J. C., 1974). Later evidence indicates that pain modulation is not limited to inhibition. Descending pathways also facilitate pain transmission at the spinal level (Ren, K. *et al.*, 2000; Millan, M. J., 2002; Gebhart, G. F., 2004). Most recently, studies have been moved to address the role of pain modulatory circuitry in persistent, or chronic pain conditions. New lines of evidence suggest that the descending pathways exhibit dramatic plasticity and multiplicity and are actively involved in the development of persistent pain after tissue or nerve injury (Porreca, F. *et al.*, 2002; Ren, K. and Dubner, R., 2002; Gebhart, G. F., 2004; Vanegas, H. and Schaible, H.-G., 2004).

5.49.2 Organization of Descending Pathways

There are multiple brain sites and pathways that are involved in descending pain modulation, ranging from the cerebral cortex to caudal medulla (Fields, H. L. and Basbaum, A. I., 1978; 1999; Gebhart, G. F., 1988; Oliveras, J. L. and Besson, J. M., 1988; Sandkuhler, J., 1996; Willis, W. D. and Westlund, K. N., 1997; Millan, M. J., 2002) (Figure 2). To date, the most well characterized endogenous pain modulatory pathway involves a circuitry linking the midbrain PAG, rostral ventromedial medulla (RVM), and the spinal cord. The second important source of descending pain control is from the dorsolateral pontomesencephalic tegmentum (DLPT), which includes the cuneiform nucleus in the midbrain ventrolateral to PAG and locus coeruleus/subcoeruleus (LC/SC) together with other neighboring noradrenaline cell groups (Fields, H. L. and Basbaum, A. I., 1999). In the caudal medulla, ventrolateral medulla (CVLM) including lateral reticular nucleus (LRN), the subnucleus reticularis dorsalis (SRD), and the nucleus tractus solitarius (NTS) have been identified to play a role in descending pain control. Additionally, hypothalamus and other forebrain sites also participate in descending pain modulation.

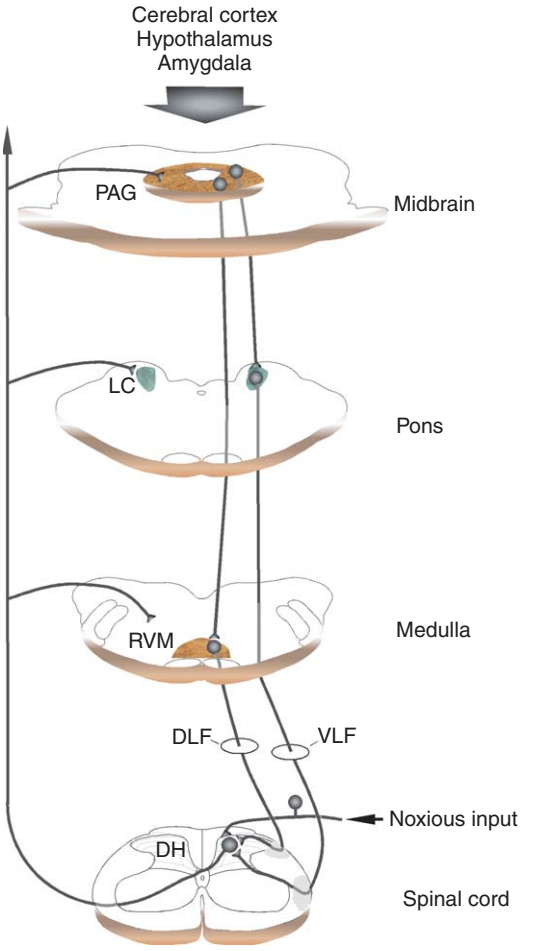

Figure 2 Two major brainstem descending pathways involved in pain modulation. The PAG in the midbrain has efferent projection to the rostral ventromedial medulla (RVM) and locus coeruleus (LC). The RVM and LC directly project to the spinal dorsal horn (DH) where nociceptive input is initially processed. The descending input from the RVM and LC travels in the dorsolateral (DLF) and ventrolateral funiculus (VLF) and modulates spinal pain transmission (only postsynaptic modulation of dorsal horn projection neuron is shown). Supraspinal projecting neurons also issue collaterals to reach pain modulatory structures and the PAG also receives input from forebrain structures including cerebral cortex, hypothalamus, and amygdala. See text for details of other key structures and pathways related to descending pain control. The drawings of brain tissue sections are adapted from Paxinos, G. and Watson, C. 2005. The Rat Brain in Stereotaxic Coordinates, 5th edn. Academic Press.

5.49.2.1 Key Structures and Pathways

5.49.2.1.1 Midbrain PAG matter

PAG neurons are organized in longitudinal columns that function to integrate behavioral responses to noxious and stressful stimuli (Bandler, R. and Shipley, M. T., 1994; Cameron, A. A. *et al.*, 1995a; 1995b). The dorsal raphe nucleus ventromedial to the cerebral aqueduct and the cuneiform nucleus lateral to the ventrolateral PAG are also considered a functional entity with PAG for descending pain control (Jensen, T. S. and Gabhart, G. F., 1988; Fields, H. L. and Basbaum, A. I., 1999). The anatomical studies implicate the importance of the midbrain PAG in descending pain modulation. Ascending fibers from the spinal cord including axons of lamina I neurons terminate in the PAG (Menetrey, D. *et al.*, 1982; Hylden, J. L. K. *et al.*, 1986; Azkue, J. J. *et al.*, 1998). Afferent input from the cerebral cortex, hypothalamus, the cuneiform nucleus, caudal brainstem nuclei such as nucleus raphe magnus (NRM), also enters PAG (Beitz, A. J., 1982b). The PAG provides major input to most areas that are involved in endogenous pain control, including RVM, LC/SC, A5, pontine parabrachial nuclei (PB), NTS, hypothalamus and amygdala (Jensen, T. S. and Gabhart, G. F., 1988; Fields, H. L. and Basbaum, A. I., 1999). The PAG

also is a site for regulation of other homeostatic functions (Gauriau, C. and Bernard, J. F., 2002). For instance, PAG neurons are activated by cardiovascular input (Murphy, A. Z. *et al.*, 1995). Somatovisceral interaction may occur in distinct organized columns of neurons in the PAG.

Animal studies have demonstrated that electrical stimulation of PAG produces profound antinociception, or analgesia (Reynolds, D. V., 1969; Mayer, D. J. *et al.*, 1971, Mayer, D. J. and Liebeskind, J. C., 1974; Fardin, V. *et al.*, 1984a). The stimulation-produced analgesia was not due to a generalized sensory and motor deficit. The animals could move and were responsive to audiovisual stimuli during stimulation, while the responses to noxious stimuli were absent. Stimulation of PAG also selectively inhibits responses of dorsal horn and trigeminal sensory neurons to noxious stimulus (Sessle, B. J. *et al.*, 1981; Dostrovsky, J. O. *et al.*, 1983; Gebhart, G. F., 1988). The stimulus-produced analgesia has been successfully observed in humans with chronic intractable pain. Electrical stimulation of the midbrain periaqueductal and hypothalamus periventricular areas produces long-standing analgesia from very brief periods of stimulation. With implanted electrodes in the brain, some patients can self-stimulate for 10–15 min, two to three times per day for adequate pain control (Kumar, K. *et al.*, 1997). It has been observed in patients who have had failure of the implanted stimulation system, that the actual return of pain to its original pre-stimulation level takes 10 days to 2 weeks (Kumar, K. *et al.*, 1997). This would indicate that activation of the endogenous pain control system has a long-lasting effect.

5.49.2.1.2 PAG–RVM–spinal dorsal horn circuitry

Convergent lines of evidence indicate that PAG stimulation-produced analgesia is relayed through other brainstem nuclei. The RVM has been identified as the premier relay station between the PAG and spinal dorsal horn. The RVM is termed for collective structures that are functionally involved in descending pain modulation, mainly consisting of the midline nucleus raphe magnus (NRM) and the adjacent gigantocellular reticular nucleus, alpha part (GiA). Anatomically, the raphe pallidus nucleus (Rpa) and a portion of the medial lateral paragigantocellular nucleus (LPGi) also are located in this region (Zagon, A., 1995; Paxinos, G. and Watson, C., 2005). Extensive evidence supports the critical involvement of the PAG–RVM–spinal dorsal horn pathway in descending pain control.

In the rat, suppression of NRM neurotransmission by either lesions, local anesthesia, or microinjection of the *N*-methyl-D-aspartate (NMDA) receptor antagonist reverses the spinal inhibition of nocifensive behavior produced by activation of PAG neurons (Behbehani, M. M. and Fields, H. L., 1979; Aimone, L. D. and Gebhart, G. F., 1986). Lidocaine block of the NRM blocks PAG stimulation-produced inhibition of spinal nociceptive neurons in cat (Gebhart, G. F. *et al.*, 1983).

RVM does not receive direct input from the spinal cord, although indirect spinal input can reach RVM through the adjacent Gi (Basbaum, A. I. and Fields, H. L., 1984; Fields, H. L. and Basbaum, A. I., 1999). The major source of input to the RVM is from the PAG and cuneiformis nucleus (Fardin, V. *et al.*, 1984b; Fields, H. L. and Basbaum, A. I., 1999). The ventrolateral cell column of PAG projects to NRM and the dorsolateral PAG region projects to the GiA (Cameron, A. A., *et al.*, 1995b). However, Van Bockstaele E. J. *et al.* (1991) show that injections of tracers into the dorsal PAG resulted in anterograde labeling in the NRM.

Electrical stimulation and microinjection of an opioid receptor agonist into the PAG activate NRM neurons that project to the spinal cord (Behbehani, M. M. and Pomeroy, S. L.,1978; Fields, H. L. and Anderson, S. D., 1978). The excitation of NRM neurons by injection of glutamate into the PAG is associated with an increase in nociceptive response threshold (Behbehani, M. M. and Fields, H. L., 1979).

The RVM has major projections to the spinal cord. Neurons of all subregions of RVM, NRM, GiA, and LPGi send axons to the spinal cord via the dorsolateral funiculus (DLF) (Basbaum, A. I. and Fields, H. L., 1979; 1984). The densest terminal fields of RVM descending fibers are in superficial and deep dorsal horn where nociceptive information is processed.

Activation of RVM neurons produces antinociception. In the cat, electrical stimulation of NRM completely suppresses the behavioral responses to noxious pinch of the skin and modifies the jaw-opening reflex threshold to tooth pulp stimulation (Oliveras, J. L. *et al.*, 1975). Electrical stimulation of NRM or opioid microinjection inhibits activity of dorsal horn nociceptive neurons (Fields, H. L. and Anderson, S. D., 1978; Dickenson, A. H. *et al.*, 1979; Jones, S. L. and Light, A. R., 1990).

The DLF mediates descending modulation of dorsal horn substantia gelatinosa neurons (Cervero, F. *et al.*, 1979). Spinal DLF lesions block antinociception produced by brainstem stimulation (Basbaum, A. I. *et al.*, 1977).

Thus, although studies suggest that some PAG neurons project directly to the spinal cord and spinal trigeminal nucleus (Mantyh, P. W. and Peschanski, M., 1982; Mantyh, P. W., 1983; Skirboll, L. *et al.*, 1983; Li, Y. Q. *et al.*, 1993), the RVM relay is necessary for the analgesic effect of PAG. Whether PAG can modulate dorsal horn sensory transmission through a direct pathway to the spinal cord still needs to be determined.

5.49.2.1.3 Dorsolateral pontomesencephalic tegmentum

In addition to the PAG–RVM–dorsal horn circuitry, the components of the DLPT constitute separate parallel descending pathways responsible for pain modulation (Dubner, R. and Bennett, G. J., 1983; Gebhart, G. F., 1988; Fields, H. L. and Basbaum, A. I., 1999). One member of the DLPT, the cuneiform nucleus, is located in the midbrain lateral reticular formation neighboring ventrolateral PAG and shares anatomical and physiological similarities with PAG related to descending pain modulation. Electrical stimulation of the midbrain lateral reticular formation produces powerful inhibition of dorsal horn nociceptive neurons in cats (Carstens, E. *et al.*, 1980). The other members of the DLPT consist of LC/SC, A7 cell group, PB and Kölliker-Fuse nuclei. The critical role of these pontine noradrenaline cell groups in descending control has been established.

5.49.2.1.3.(i) The PAG–LC/SC–spinal pathway

The LC in the dorsal pontine is the major noradrenergic nucleus originally designated the A6 cell group by Dahlström A. and Fuxe K. (1964). The SC is located immediately ventral to the LC and assigned to the A7 noradrenaline cell group by Westlund K. N. *et al.* (1983). Since the two structures are relatively small and the spinal projecting fibers from the LC are mainly from the ventral part, electrical stimulation will affect both nuclei (Jones, S. L., 1991). The following studies provide evidence that the LC/SC–spinal pathway represents an additional source of descending pain modulation.

The LC/SC neurons project to the spinal cord. Initially, bulbospinal noradrenergic fibers are thought to originate from the A1 cell group in the caudal medulla (Dahlström, A. and Fuxe, K., 1964). Using combined dopamine–beta-hydroxylase immunohistochemistry and retrograde tracing, Westlund K. N. *et al.* (1983) demonstrated that brainstem descending noradrenergic fibers are exclusively from the pontine noradrenergic cell groups. In the rat, the LC and SC provide major descending noradrenergic axons to the spinal cord. These findings form the anatomical basis for a role of the LC/SC in descending control. One concern on the spinal projection of LC/SC neurons is that they apparently terminate most heavily in laminae VII, VIII, and IX of the ventral horn. The termination of LC fibers is moderate in the deep dorsal horn and relatively sparse in the superficial dorsal horn (Clark, F. M. and Proudfit, H. K., 1991). However, there appears to be a substrain difference in LC/SC descending projection related to the commercial sources. More lamina I terminations are from the LC in rats raised in Harlan Sprague-Dawley while the SC of Sasco source provides more lamina I projection (Fritschy, J. M. and Grzanna, R., 1990; Sluka, K. A. and Westlund, K. N., 1992; Willis, W. D. *et al.*, 1995; Proudfit, H. K., 2002).

LC/SC stimulation produces inhibition of dorsal horn nociceptive neurons in rats and cats (Mokha, S. S. *et al.*, 1986; Jones, S. L. and Gebhart, G. F., 1986; Jones, S. L., 1991). Selective spinal lesions indicate that the effect of LC/SC is mediated by the ventrolateral funiculus (VLF) (Jones, S. L., 1991), whereas the NRM stimulation-produced inhibition is conveyed via the DLF (Basbaum, A. I. *et al.*, 1977).

Unlike the PAG, the effect of LC on spinal nociceptive transmission is not mediated through RVM since local anesthesia of NRM does not block LC stimulation-produced inhibition of dorsal horn neurons (Jones, S. L., 1991).

Intrathecal yohimbine, an alpha 2 adrenoceptor antagonist, blocks the LC stimulation-produced inhibition of nociceptive reflex in rats (Gebhart, G. F., 1988).

The LC/SC may also relay the effect of PAG since they receive PAG input. In monkey, dense projection to the LC is identified from the PAG (Mantyh, P. W., 1983). In rat, the dorsolateral PAG cell column innervates LC/SC (Cameron, A. A. *et al.*, 1995b), although another study suggests that PAG does not have major projections to the LC proper (Ennis, M. *et al.*, 1991).

5.49.2.1.3.(ii) Other noradrenaline cell groups in the DLPT participating in descending modulation

5.49.2.1.3.(ii).(a) A7 cell column The A7 cell group spans rostrocaudally the caudal midbrain and

rostral pons in the rat (Paxinos, G. and Watson, C., 2005). The rostral tip of the A7 group can be seen at the same transverse plane as the cuneiform nucleus and PAG. In the pons, the A7 is located medial to the dorsal part of the ventrolateral principal sensory trigeminal nucleus and ventral to the supratrigeminal and Kölliker-Fuse nuclei. The caudal A7 cells end before the appearance of the LC. The A7 cells also provide dense projection to the spinal cord (Westlund, K. N. *et al.*, 1983). This cell group may play a unique role in the descending circuitry. The A7 group has reciprocal connections with RVM and may mediate some effect of RVM on spinal nociceptive transmission (Fields, H. L. and Basbaum, A. I., 1999; Buhler, A. V. *et al.*, 2004).

5.49.2.1.3.(ii).(b) Parabrachial nucleus The PB consists of several distinct subnuclei located in the dorsolateral pons and belongs to the pontine cell groups that give rise to noradrenergic terminals in the spinal cord (Westlund, K. N. *et al.*, 1983). The PB has been demonstrated as an important relay station in pain pathways. Spinal and subnucleus caudalis lamina I nociceptive neurons project to PB (Hylden, J. L. K. *et al.*, 1989; Bester, H. *et al.*, 2000). PAG neurons project to the PB in the rat (Krout, K. E. *et al.*, 1998). The PB has further connections with the amygdala (Bernard, J. F. *et al.*, 1993) and the hypothalamus (Bester, H. *et al.*, 1997), and sends descending projections to the spinal and medullary dorsal horn (Yoshida, A. *et al.*, 1997). The activation of the PB descending pathway modulates spinal and trigeminal nociceptive transmission (Girardot, M. N. *et al.*, 1987; Chiang, C. Y. *et al.*, 1994; Willis, W. D. and Westlund, K. N., 1997).

5.49.2.1.3.(ii).(c) The Kölliker-Fuse nucleus The Kölliker-Fuse nucleus is immediately dorsal to the A7 cell group (Paxinos, G. and Watson, C., 2005) and is the major source of spinopetal noradrenergic fibers in the cat (Stevens, R. T. *et al.*, 1982). The Kölliker-Fuse nucleus is more developed in humans than in other animal species (Lavezzi, A. M. *et al.*, 2004). Young R. F. *et al.* (1992) show that chronic stimulation of the Kölliker-Fuse nucleus region can relieve intractable pain in patients and the effect is comparable to that of PAG/periventricular stimulation.

5.49.2.1.3.(ii).(d) A5 cell column The A5 cell group spans the ventrolateral pontine tegmentum at the mid-pon level to the rostral ventrolateral medulla (RVLM) in the rat. This cell group shares many similarities with other noradrenergic cell groups in the DLPT such as spinal projection (Westlund, K. N. *et al.*, 1983; Clark, F. M. and Proudfit, H. K., 1993) and extensive connections with other pain modulatory nuclei including PAG and CVLM (Cameron, A. A. *et al.*, 1995b; Tavares, I. and Lima, D., 2002). Stimulation of the A5 produces inhibition of the nociceptive tail flick reflex in rats and the effect is mediated through spinal opioid and alpha adrenoceptors (Burnett, A. and Gebhart, G. F., 1991). Since A5 has been primarily considered as an important site for cardiovascular regulation, this cell group may play a role in somatoautonomic integration.

5.49.2.1.4 Caudal medulla

Several structures in the caudal medulla have emerged as important players in endogenous pain control. As these sites overlap with those critical in visceral and cardiovascular functions, the caudal medulla provides a point of convergence to facilitate interactions between somatosensory and autonomic regulation.

5.49.2.1.4.(i) Caudal ventrolateral medulla Anatomically, the CVLM is not a clearly defined structure, the center of which is about 2 mm ventral to the dorsal surface of the medulla and medial to the ventral pole of the spinal trigeminal nucleus in the rat. Rostrocaudally, the CVLM is within the most caudal segment of the medulla starting from approximately 0.5 mm rostral to the calamus scriptorius (Aicher, S. A. *et al.*, 1996). This region is also referred as the lateral reticular formation and includes the A1 catecholamine cell group. The poorly defined ventromedial border of lamina V of the trigeminal subnucleus caudalis may fall into the territory of the CVLM, or vice versa. It has been consistently observed that a variety of noxious stimuli, including noxious heating of the hindpaw, peritoneal inflammation, urinary bladder inflammation, deep muscle irritation or inflammation, all induce Fos protein expression in the CVLM (see Ren, K., 2002).

5.49.2.1.4.(i).(a) Lateral reticular nucleus The LRN is a large nucleus located bilaterally in the ventrolateral medullary reticular formation. It receives input from a variety of structures including PAG and NRM and projects to the spinal cord (Janss, A. J. and Gebhart, G. F., 1987; Lee, H. S. and Mihailoff, G. A., 1999). Electrical or chemical stimulation of the LRN produces inhibition of

the nociceptive reflex and spinal dorsal horn unit responses to noxious stimuli. The LRN-produced descending inhibition is partially mediated by bilateral DLF and spinal alpha 2 adrenergic and serotonin receptors (Janss, A. J. and Gebhart, G. F., 1987; 1988).

5.49.2.1.4.(i).(b) Lateral CVLM The CVLMlat, a small area of the medullary reticular formation between the ventral pole of the spinal trigeminal nucleus and LRN, has recently been proposed to have a major role in descending pain inhibition (Tavares, I. and Lima, D., 2002). The CVLMlat has reciprocal connections with spinal lamina I neurons and output to the A5 cell group and RVM. These indirect spinopetal pathways from the CVLMlat via A5 and RVM may mediate noradrenergic and serotonergic antinociception produced by CVLM activation. Neurons in this region are reciprocally connected to the RVM and activated after orofacial tissue injury (Sugiyo, S. *et al.*, 2005). A group of reticulohypothalamic tract neurons in the CVLM may overlap with the CVLMlat (Malick, A. *et al.*, 2000). Most of these neurons respond to both innocuous and noxious stimulation of the head but only to noxious stimulation of extracephalic regions. Their response properties suggest that they participate in pain modulation.

5.49.2.1.4.(ii) Subnucleus reticularis dorsalis The SRD includes a group of neurons distributed in the dorsal medullary reticular formation medial to the trigeminal subnucleus caudalis (also called medullary reticular nucleus, dorsal part, MdD) (Paxinos, G. and Watson, C., 2005). The SRD contributes to the spinoreticular–thalamic pathway by receiving nociceptive information from the spinal dorsal horn and relays it to the thalamus (Villaneuva, L., *et al.* 1998). The diffuse noxious inhibitory control (DNIC), proposed by Le Bars and colleagues, is mediated via the SRD and independent of the RVM-spinal pathway (Bouhassira, D. *et al.*, 1992; 1993). The SRD is also proposed as a pronociceptive center (Lima, D. and Almeida, A., 2002).

5.49.2.1.4.(iii) Nucleus tractus solitarius The NTS is a key structure in somatovisceral processing, since this nucleus receives somatic and visceral input and has extensive efferent connections with other nuclei (Randich, A. and Maixner, W., 1984; Ren, K. *et al.*, 1990). Notably, PAG neurons project to NTS (Cameron, A. A. *et al.*, 1995b). Activation of NTS neurons produces descending pain inhibition and the vagal afferent modulation of nociception is mediated through NTS (Randich, A. and Gebhart, G. F., 1992). The function of NTS supports somatovisceral and somatoautonomic interactions.

5.49.2.1.5 Forebrain sites

A number of forebrain structures provide descending input to brainstem nuclei, particularly the PAG (Beitz, A. J., 1982b).

5.49.2.1.5.(i) Hypothalamus The subregions of the hypothalamus provide the largest descending input to the PAG (Beitz, A. J., 1982b). The periventricular gray (PVG) of the hypothalamus is the rostral extension of PAG and rich in opioids. Axons of PVG neurons can reach the spinal cord (Jensen, T. S. and Gabhart, G. F., 1988; Van den Pol, A. N. and Collins, W .F., 1994). Stimulation of PVG can produce effective pain relief in patients (Kumar, K. *et al.*, 1997). The lateral hyphthalamus (LH) has reciprocal connections with the PAG and NRM (Aimone, L. D. *et al.*, 1988; Cameron, A. A. *et al.*, 1995a; 1995b). Inhibition of spinal nociceptive transmission from the LH requires a bulbar relay in the NRM (Aimone, L. D. *et al.*, 1988).

5.49.2.1.5.(ii) Amygdala The ascending nociceptive input reaches the amygdala through a relay in the PB (Gauriau, C. and Bernard, J. F., 2002). The amygdala has reciprocal connections with PAG (Rizvi, T. A. *et al.*, 1991). Activation of amygdala neurons produces analgesia that is mediated through PAG (see Fields, H. L. and Basbaum, A. I., 1999). The dorsal PAG interacts with the amygdala to affect fear and anxiety and the amygdala is an important site for interrelating sensory and affective dimensions of pain (Behbehani, M. M., 1995; Price, D. D., 2002).

5.49.2.1.5.(iii) Cerebral cortex Recent brain imaging studies have generated a wealth of information on activation of the cortical areas during pain processing. It also shows that the cerebral cortex is not only the end point of the pain pathway, but also a source of descending input that contributes to the fine-tuning of pain threshold and modulation of the emotional aspect of pain (Jasmin, L. *et al.*, 2003b; Petrovic, P. *et al.*, 2004). One interesting pathway involves the anterior cingulate cortex (ACC) and amygdala in pain modulation. The ACC–amygdala pathway may modulate pain-related stress and aversive responses, as well as pain-related fear memory (Gao, Y. J. *et al.*, 2004; Petrovic, P. *et al.*,

2004; Tang, J. *et al.*, 2005). Transcranial magnetic stimulation of the dorsolateral prefrontal cortex increased human pain tolerance level (Graff-Guerrero, A. *et al.*, 2005).

5.49.2.1.6 Summary

It is clear from the above overview that the pivotal anatomical substrates for descending pain control are located within the brainstem. In addition to the midbrain PAG, a number of important sites are in the medulla. The medulla oblongata is classically termed the vital center for life with its critical involvement in cardiovascular and respiratory controls. Since pain is arguably one of the most important body functions for survival, it is not surprising that the structures that are vital for pain modulation are also located in the medulla to facilitate interactions between somatosensory and autonomic regulation. The interplay of the descending system with visceral (NTS-PB), cardiovascular (CVLM, A5, PAG), respiratory (Kölliker-Fuse nucleus), micturation (RVM, pons), arousal (A6), and emotional (amygdala, ACC) regulation is extensive and serves to enhance survival (Randich, A. and Maixner, W., 1984; Randich, A. and Gebhart, G. F., 1992; Murphy, A. Z. *et al.*, 1995; Mason, P., 2001).

5.49.2.2 Neurotransmitters

A plethora of transmitters (also see Chapter Pharmacological Modulation of Pain) have been shown to be involved in descending pain control (Duggan, A. W., 1985; Fields, H. L. *et al.*, 1991; Millan M. J., 2002). The most studied and established candidates include endogenous opioid peptides, noradrenaline, and serotonin (5-HT). All these transmitters participate in inhibition and facilitation of pain transmission through their respective receptor subtypes. The major neurotransmitters that are implicated in descending pain control are briefly discussed below.

5.49.2.2.1 Endogenous opioids and related peptides

5.49.2.2.1.(i) Opioid peptides

Tsou K. and Jang C. S. (1964) discovered that the most sensitive sites for the analgesic action of morphine were located in the PAG and the adjacent hypothalamic periventricular area. These early findings suggested that opiate drugs like morphine acted by binding to a receptor in the brain and that there likely were endogenous ligands or chemical mediators whose actions were mimicked by opiates. Opiate binding sites in the brain were subsequently demonstrated in early 1970s by radioligand binding assays (Pert, C. B. and Snyder, S. H., 1973; Simon, E. J. *et al.*, 1973; Terenius, L., 1973) and the first endogenous opioid peptides enkephalins were identified soon after (Hughes, J. *et al.*, 1975). To date, four classes of opioid peptides have been found in the brain: endorphins, enkephalins, dynorphins, and endomorphins (Hughes, J. *et al.*, 1975; Li, C. H. and Chung, D., 1976; Goldstein, A. *et al.*, 1979; Zadina, J. E. *et al.*, 1997). Martin W. R. *et al.* (1976) first proposed the existence of three subtypes of opioid receptors based on three different syndromes produced by congeners of morphine. All three opioid receptors, μ (MOP), δ (DOP), and κ (KOP), have now been cloned (Evans, C. J. *et al.*, 1992; Kieffer, B. L. *et al.*, 1992; Chen, Y. *et al.*, 1993; Meng, F. *et al.*, 1993). The endogenous opioid peptides and their respective precursors, amino acid sequence, and preferred receptor subtypes are summarized in Table 1. Recent studies also indicate the existence of alternative splicing (Pan, L. *et al.*, 2005), subtypes of the mu, delta, and kappa receptors (Fowler, C. J. and Fraser, G. L., 1994;

Table 1 Endogenous opioid peptides involved in pain modulation

Precursor	*Name*	*Amino acid sequence*	*Receptor*
POMC (pro-opiomelanocortin)	β-Endorphin	Tyr-Gly-Gly-Phe-Met-Thr-Ser-Glu-(human) Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Asn-Ala-Ile-Ile-Lys-Asn-Ala-Tyr-Lys-Lys-Gly-Glu-OH	$\mu \geq \delta$
Proenkephalin	Leu-enkephalin	Tyr-Gly-Gly-Phe-Leu-OH	$\delta \geq \mu$
Proenkephalin	Met-enkephalin	Tyr-Gly-Gly-Phe-Met-OH	$\delta \geq \mu$
Prodynorphin	Dynorphin A	Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile-Arg-Pro-Lys-Leu-Lys-Trp-Asp-Asn-Gln-OH	κ
Unidenitified	Endomorphin-1	Tyr-Pro-Trp-Phe-NH_2	μ
Unidenitified	Endomorphin-2	Tyr-Pro-Phe-Phe-NH_2	μ

Zaki, P. A. *et al.*, 1996; Pasternak, G. W., 2001), and opioid receptor gene polymorphism (Ikeda, K. *et al.*, 2005). The functional significance of the further molecular diversity of opioid receptor subtypes in descending pain control is poorly understood.

The endogenous opioids and their receptors are distributed in structures involved in descending pain control at all levels including the amygdala, hypothalamus, PAG, DLPT, RVM, and spinal cord (Basbaum, A. I. and Fields, H. L., 1984; Ruda, M. A., 1988; Mansour, A. *et al.*, 1995; Fields, H. L. and Basbaum, A. I., 1999; Wang, H. and Wessendorf, M. W., 2002). Notably, beta-endorphin terminals from hypothalamus descend along the borders of the third ventricle and reach PAG, DLPT, and NRM (Finley, J. C. *et al.*, 1981; Jensen, T. S. and Gabhart, G. F., 1988). Rostral ventromedial medulla neurons express multiple opioid receptor phenotypes (Marinelli, S. *et al.*, 2002). In the RVM, spinally projecting serotonergic and nonserotonergic neurons express mu- and delta-opioid receptor mRNAs (Wang, H. and Wessendorf, M. W., 1999). Enkephalinergic axons in the spinal cord synapse with thalamic projection neurons (Ruda, M. A., 1982), providing postsynaptic modulation of ascending nociceptive information.

Microinjection of morphine into the PAG produces behavioral analgesia (Camarata, P. J. and Yaksh, T. L., 1985). Brain stimulation-produced analgesia can be reversed by naloxone, an opioid receptor antagonist (Akil, H. *et al.*, 1976). Behavioral analgesia produced by an opioid receptor agonist is related to the inhibition of spinal nociceptive neurons (Yaksh, T. L., 1978). However, the effect of opioid agonists on dorsal horn nociceptive neurons is more variable and can be both inhibitory and facilitatory (Gebhart, G. F., 1982; Stamford, J. A., 1995). This paradox is likely related to the sampling limitation during single unit recording and cautions on predicting behavioral outcome from activity of single neurons. Using Fos immunoreactivity to study a population of activated neurons simultaneously, opioids produce behavioral analgesia that is correlated to an inhibition of dorsal horn neuronal activation as indicated by a reduction of noxious stimulus-induced Fos immunoreactivity (Gogas, K. R. *et al.*, 1991). Is the endogenoous opioid system tonically active? The findings from opioid receptor knockout mice suggest a low endogenous opioid tone with each receptor subtype contributing differentially to the modulation of transient pain (Matthes, H. W. *et al.*, 1996; Sora, I. *et al.*, 1997; Gaveriaux-Ruff, C. and Kieffer, B. L., 2002).

Although there is no question that opioids produce potent pain inhibition through their respective receptors at all levels of the descending circuitry, the role of spinopetal opioidergic fibers in mediating descending modulation from supraspinal sites has yet to be convincingly demonstrated. Intrathecal administration of the opioid receptor antagonists in rats has been shown to reverse or attenuate analgesia produced by intracerebroventricular morphine (Gogas, K. R. *et al.*, 1996), intra-PAG injection of beta-endorphin (Tseng, L. F. and Tang, R., 1990), electrical stimulation of the RVM (Zorman, G. *et al.*, 1982; Lu, Y. *et al.*, 2004), or the hypothalamic arcuate nucleus (Wang, Q. *et al.*, 1990). However, the contribution of intrinsic opioidergic interneurons in the spinal dorsal horn to supraspinal-produced analgesia cannot be ruled out. In the cat, opioid peptides intrinsic to the spinal cord play a major role in inhibition of spinal nociceptive transmission (Duggan, A. W., 1985).

5.49.2.2.1.(ii) Orphanin FQ, nocistatin, and neuropeptideFF Orphanin FQ, or nociceptin, is a heptadecapeptide that was identified as the endogenous ligand for the orphan-opioid-receptor-like 1 (ORL-1, now nociceptin/orphanin FQ peptide receptor, NOP) receptor (Meunier, J. C. *et al.*, 1995; Reinscheid, R. K. *et al.*, 1995). Genetically, Orphanin FQ and NOP belong to the same family with the opioids and their receptors and they share homology with dynorphin A and the kappa opioid receptor, respectively. However, orphanin FQ does not interact with three classical opioid receptors, largely due to the replacement of the first tyrosine residue by phenylalanine. Most studies show that orphanin FQ produces analgesia at the spinal level and both pro- and anti-nociception supraspinally (Meunier, J. C., 1997; Henderson, G. and McKnight, A. T., 1997). However, intrathecal low dose of orphanin FQ also produces allodynia (Yamamoto, T. *et al.*, 1999). Orphanin FQ can suppress both pain facilitatory and inhibitory neurons in the RVM, which may explain its dual effects on pain processing under different conditions (Pan, Z. Z. *et al.*, 2000; Vaughan, C. W. *et al.*, 2001; Heinricher, M. M., 2005).

Nocistatin is liberated from the same orphanin FQ precursor protein, proorphanin, after posttranslational cleavage but binds to a receptor distinct from NOP (Okuda-Ashitaka, E. *et al.*, 1998). Nocistatin opposes action of orphanin FQ, and can be considered a functional antagonist of orphanin FQ

(Yamamoto, T. *et al.*, 1999; Millan, M. J., 2002). Proorphanin also yields another heptadecapeptide, orphanin FQ2, which may participate in pain inhibition (Rossi, G. C. *et al.*, 1998).

The octapeptide neuropeptideFF (NPFF, Phe-Leu-Phe-Gln-Pro-Gln-Arg-Phe-NH_2) is originally isolated from the bovine brain and found to possess anti-morphine property (Yang, H. Y. *et al.*, 1985). NPFF fibers project to the PAG from hypothalamus and to the RVM from the NTS (Aarnisalo, A. A. and Panula, P., 1995). In the spinal cord, NPFF-immunoreactive cell bodies and terminals are localized to laminae I–IV and X and DLF, but a supraspinal origin of NPFF was not found (Kivipelto, L. and Panula, P., 1991). Available evidence indicates that NPFF produces antinociception at the spinal level and pronociception (anti-opioid) at the supraspinal level (Millan, M. J., 2002; Mollereau, C. *et al.*, 2005).

5.49.2.2.2 Monoamines

It is now well established that descending monoaminergic fibers mediate descending modulation from the supraspinal sites (Yaksh, T. L., 1979; Basbaum, A. I. and Fields, H. L., 1984; Gebhart, G. F., 1988; Tjolsen, A. *et al.*, 1991; Hung, K. C. *et al.*, 2003). The major pathways involve noradrenergic fibers from the DLPT and serotonergic fibers from the NRM, the major nucleus of RVM. The two pathways can be co-activated and may act synergistically to participate in descending pain modulation (Gebhart, G. F., 1988; Sawynok, J., 1989; Danzebrink, R. M. and Gebhart, G. F., 1991).

5.49.2.2.2.(i) Noradrenaline Intrathecal administration of the alpha 2-adrenoceptor antagonist yohimbine, but not the nonselective opioid receptor antagonist naloxone and alpha 1 adrenoceptor antagonist prazosin, attenuates descending inhibition of nocifensive tail flick reflex produced by focal stimulation of the LC/SC region (Jones, S. L., 1991). The PAG-produced inhibition of dorsal horn neurons is reduced by microdialysis of alpha 2 adrenoceptor antagonists idazoxan and yohimbine into the dorsal horn (Peng, Y. B. *et al.*, 1996). Selective depletion of spinal noradrenaline by intrathecal DSP4 attenuates morphine analgesia (Zhong, F. X. *et al.*, 1985). These results clearly indicate a role of spinopetal noradrenergic fibers in descending modulation since there are no noradrenaline-producing cell bodies in the spinal cord (Swanson, L. W. and Hartman, B. K., 1975). Consistently, depletion of spinal NA by 6-hydroxydopamine decreases and intrathecal NA elevates the nociceptive threshold (Reddy, S. V. *et al.*, 1980). Opioid analgesia is enhanced in norepinephrine transporter knockout mice and the effect is blocked by yohimbine (Bohn, L. M. *et al.*, 2000). Intrathecal administration of the adrenoceptor antagonists produces a decrease in nociceptive threshold in the rat, suggesting that the descending noradrenergic system is tonically active (Sagen, J. and Proudfit, H. K., 1984). The antinociceptive effect of NA in the spinal cord does not appear to require GABAergic, glycinergic, opioidergic, and serotonergic activity (Reddy, S. V. *et al.*, 1980), and may involve both pre- and postsynaptic mechanisms (Sonohata, M. *et al.*, 2004). *In vivo* whole-cell patch-clamp recordings from rat substantia gelatinosa neurons show that NA reduces EPSC and suppresses action potentials evoked by a noxious stimulus, an effect that is blocked by antagonism of alpha 2, but not alpha 1, adrenoceptors (Sonohata, M. *et al.*, 2004).

Studies using transgenic mice, such as D79N mice with a point mutation of the alpha 2A adrenoceptors, have examined the subtypes of spinal alpha 2 adrenoceptors involved in descending inhibition. Most studies support a role for the alpha 2A subtype in spinal analgesia (Hunter, J. C. *et al.*, 1997; Lakhlani, P. P. *et al.*, 1997; Stone, L. S. *et al.*, 1997; Kingery, W. S. *et al.*, 2000; Malmberg, A. B. *et al.*, 2001; Mansikka, H. *et al.*, 2004; Ozdogan, U. K. *et al.*, 2004). However, alpha 2C adrenoceptor-bearing terminals synapse with NK-1 projection cells in the rat dorsal horn (Olave, M. J. and Maxwell, D. J., 2003), suggesting a role in postsynaptic modulation. The alpha 2C adrenoceptors have been shown to be involved in spinal analgesia and adrenergic–opioid synergy (Fairbanks, C. A. *et al.*, 2002; Lahdesmaki, J. *et al.*, 2003). The alpha 2B adrenoceptors may play an important role in the pontine noradrenergic nuclei involved in analgesic action of nitrous oxide (Sawamura, S. *et al.*, 2000).

After peripheral nerve injury, there is a decrease in alpha 2A mRNA and protein immunoreactivity in the spinal cord of the rat (Stone, L. S. *et al.*, 1999; Leiphart, J. W. *et al.*, 2003); these findings suggesting a reduced noradrenergic transmission in these rats. However, there is also an increased descending noradrenergic innervation to the spinal dorsal horn after nerve injury, possibly serving to enhance inhibition (Ma, W. and Eisenach, J. C., 2003). Interestingly, pain hypersensitivity after nerve injury develops similarly in the wild-type mice and those with mutation of alpha 2A, 2B, or 2C adrenoceptors, suggesting that

the net inhibitory tone is not affected by loss of alpha 2 adrenoceptors (Malmberg, A. B. *et al.*, 2001). It is worth noting that, different from previous observations in normal rats (Sagen, J. and Proudfit, H. K., 1984), the baseline nociceptive threshold is not affected in mice with mutation of either of the three alpha 2 subtypes (Malmberg, A. B. *et al.*, 2001), suggesting that compensatory mechanisms may have developed in the mutant mice to balance the loss of tonic noradrenergic inhibition.

In contrast to a predominant inhibitory role of the alpha 2 adrenoceptors, the alpha 1 adrenoceptor may be involved in descending pain facilitation (Holden, J. E. *et al.*, 1999; Nuseir, K. and Proudfit, H. K., 2000; Hedo, G. and Lopez-Garcia, J. A., 2001; Holden, J. E. and Naleway, E., 2001) and supraspinal pronociceptive action (Kingery, W. S. *et al.*, 2002). Intracellular recordings from adult rat spinal slice support the opposing actions of NA on substantia gelatinosa neurons. Noradrenaline induces hyperpolarization or increased spontaneous excitatory postsynaptic potentials in subpopulations of dorsal horn neurons, which is selectively blocked by alpha 2 (yohimbine) and alpha 1 (prazosin) adrenoceptor antagonists, respectively (North, R. A. and Yoshimura, M., 1984).

5.49.2.2.2.(ii) Serotonin There is dense serotonergic innervation in the spinal dorsal horn (Ruda, M. A. *et al.*, 1982; Ruda, M. A., 1988), which is almost exclusively derived from supraspinal sources (LaMotte, C. C., 1988; Fields, H. L. *et al.*, 1991; Mason, P., 2001; Millan, M. J., 2002). The NRM is the major structure that issues descending serotonergic fibers to the spinal cord (Bowker, R. M. *et al.*, 1988), although not all descending axons from the NRM are serotonergic (Jones, S. L. and Light, A. R., 1992; Wang, H. and Wessendorf, M. W., 1999). Descending inhibition produced by focal electrical stimulation in the PAG or NRM is mediated in part by descending serotonergic pathways acting on spinal serotonergic receptors. Microinjection of morphine into the PAG and stimulation of NRM evokes the release of serotonin from spinal cord (Yaksh, T. L. and Tyce, G. M., 1979; Rivot, J. P. *et al.*, 1982). Intrathecal methysergide, a nonselective 5-HT receptor antagonist, increases the intensity of stimulation in the PAG and the NRM for inhibition of the nocifensive tail flick reflex while naloxone has no effect (Gebhart, G. F., 1988). The role of the descending serotonergic pathway in descending pain inhibition is well established (Fields, H. L. and Basbaum, A. I., 1978; Basbaum, A. I. and Fields, H. L., 1984).

It has become clear that descending serotonergic fibers also participate in facilitation of nociception (Zhuo, M. and Gebhart, G. F., 1991; Millan, M. J., 2002; Suzuki, R. *et al.*, 2002b; 2004b) The nociceptive facilitation triggered by low intensity vagal afferent stimulation involves descending serotonergic pathways (Ren, K. *et al.*, 1991). Although spinal application of 5-HT generally produces an analgesic effect, excitation of dorsal horn neurons by serotonergic agonists is also reported (Todd, A. J. and Millar, J., 1984; Zhang, Y. *et al.*, 2001). In the spinal slice preparation, serotonin can recruit silent glutamatergic synapses in the superficial dorsal horn and enhance synaptic transmission (Li, P. and Zhuo, M., 1998). This result supports a facilitatory role of descending serotonergic fibers in spinal plasticity in response to injury. Indeed, intrathecal administration of methysergide has been shown to attenuate neuropathic pain in the rat (Pertovaara, A. *et al.*, 2001). In carrageenan-inflamed rats, the facilitation of dorsal horn neuronal responses to noxious stimuli by agonists of 5-HT_{1A} and 5-HT_{1B} receptors is further enhanced (Zhang, Y. *et al.*, 2001). Blockade of spinal 5-HT_3 receptors reduces tissue injury-induced persistent pain (Zeitz, K. P. *et al.*, 2002).

At least 12 different subtypes of 5-HT receptors may be involved in pain modulation (Hoyer, D. *et al.*, 1994; Millan, M. J., 2002). However, their roles in descending pain control have only been evaluated in a few subtypes including 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2A}, 5-HT_3, and 5-HT_4 receptors (Millan, M. J., 2002). Recent studies have identified a pronociceptive role of the 5-HT_3 subtype (Suzuki, R. *et al.*, 2002b; Zeitz, K. P. *et al.*, 2002). A number of studies have indicated a facilitatory role of the 5-HT_{1A} receptor while others pointed to an opposite effect (Millan, M. J., 2002). The equivocal literature on the role of 5-HT receptors in pain modulation suggests sophisticated differential involvement of the 5-HT receptor subtypes in pain modulation and transmission. Moreover, different experimental conditions including the chosen endpoints, stimulation modality, anesthetic state, and *in vivo* versus *in vitro* preparations are also confounding factors.

Despite a well-documented contribution of the descending serotonergic pathway to pain modulation, the specific role of RVM serotonergic neurons in the operation of descending circuitry is not understood. Stimulation of the PAG that produces analgesia does not excite RVM serotonergic neurons (Gao, K. *et al.*, 1997). Thus, these cells may not mediate the signal from PAG, at least not directly.

Stimulation of NRM that induces antinociception does not release 5-HT in the spinal cord, although further increasing the stimulation intensity results in 5-HT release (Sorkin, L. S. *et al.*, 1993). These results are consistent with earlier findings that both serotonergic and nonserotonergic pathways contribute to descending inhibition (Rivot, J. P. *et al.*, 1980). Careful analysis of the characteristics of RVM serotonergic neurons revealed that their levels of activity depend on the conscious state (Mason, P., 2001). Serotonergic cells exhibit the highest level of discharge during waking when nociceptive threshold is relatively high compared to the sleep state. One hypothesis is that the descending serotonergic modulation of pain transmission is state dependent and closely related to alterations in serotonergic tone.

5.49.2.2.2.(iii) Dopamine Similar to noradrenaline and serotonin, spinal dopamine is virtually exclusively of supraspinal origin, mainly from the hypothalamus (see Millan, M. J., 2002). The dopamine receptor consists of D_1 and D_2 subtypes and they both have been localized in the spinal cord including the dorsal horn. The D_1 receptor may support opioid analgesia from PAG activation (Flores, J. A. *et al.*, 2004) and the activity of the D_2 subtype may oppose opioid analgesia (King, M. A. *et al.*, 2001). The contribution of the descending dopaminergic pathway to modulation of spinal nociceptive transmission remains to be determined.

5.49.2.2.3 Amino acids

Excitatory and inhibitory amino acid neurotransmitters are widely distributed in the pain modulatory circuitry including the PAG, DLPT, RVM, and spinal cord. They clearly participate in the process of descending pain control through actions on their respective receptors.

5.49.2.2.3.(i) Glutamate Activation of supraspinal glutamate synapses is associated with antinociception. Glutamate-containing neurons are observed in the PAG of the cat (Barbaresi, P. *et al.*, 1997). Stimulation-produced analgesia from the PAG is mediated by excitatory amino acid receptors in the RVM (Aimone, L. D. and Gebhart, G. F., 1986; van Praag, H. and Frenk, H., 1990; Spinella, M. *et al.*, 1996). Stimulation of the cuneiform nucleus excites about 50% of NRM neurons, an effect blocked by an excitatory amino acid antagonist (Richter, R. C. and Behbehani, M. M., 1991). However, microinjection of glutamate into the discrete brainstem sites including some sites in the PAG can also induce pain-like behavior via activation of NMDA receptors (Jensen, T. S. and Yaksh, T. L., 1992). Thus, the glutamatergic transmission within the pain modulatory circuitry is also capable of bidirectional pain modulation.

Glutamate receptors consist of ionotropic and metabotropic (mGluR) subfamilies. The former includes NMDA, alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainate (KA) receptor subtypes, and the eight subtypes of metabotropic glutamate receptors (mGluR's) are subdivided into three groups. Studies on the role of specific glutamate subtypes in descending pain control are still in the preliminary stage. In the PAG, group I mGluR may be involved in pain inhibition involving an interaction with NMDA receptors (Maione, S. *et al.*, 1998; Berrino, L. *et al.*, 2001). In the RVM, activation of group II mGluR produces descending inhibition of the nociceptive tail flick reflex (Kim, S. J. *et al.*, 2002). Activation of AMPA and NMDA receptors contributes to plasticity in the RVM in response to tissue injury (Urban, M. O. and Gebhart, G. F., 1999; Ren, K. and Dubner, R., 2002).

Unlike noradrenaline and serotonin, primary afferent fibers are rich in glutamate (Battaglia, G. and Rustioni, A., 1988). At the spinal level, glutamate receptors play a major role in the development of persistent pain. It is difficult to isolate the effect of descending glutamatergic input from that of primary afferent origin. Limited information is available on the anatomy of descending glutamatergic pathways. One study shows that descending pathways from the DLPT nuclei contain glutamatergic fibers (Liu, R. H. *et al.*, 1995). However, whether they contribute to descending pain modulation is unclear.

5.49.2.2.3.(ii) Gamma-aminobutyric acid and glycine In general, gamma-aminobutyric acid (GABA) and glycine are used by inhibitory interneurons. In the PAG, GABAergic terminals are abundant (Reichling, D. B. and Basbaum, A. I., 1990). Blocking GABA receptors in the ventral PAG enhances morphine-produced analgesia in this region, consistent with the view that GABAergic neurons inhibit PAG output neurons involved in descending inhibition (Depaulis, A. *et al.*, 1987). GABAergic terminals from the PAG descend to the RVM (Reichling, D. B. and Basbaum, A. I., 1990).

RVM GABA-containing neurons and GABAergic terminals of PAG neurons both synapse with spinally projecting RVM neurons (Cho, H. J. and Basbaum, A. I., 1991). Inhibition of GABAergic transmission in the RVM leads to disinhibition of pain inhibitory activity. Apparently, the GABA system may set up the tone of descending inhibition and help to maintain an adequate level of pain sensitivity, which is essential to normal body function. Direct GABAergic innervation of the spinal dorsal horn by fibers descending from the RVM has been described (Antal, M. *et al.*, 1996). However, confounded by the presence of abundant intrinsic GABAergic neurons in the spinal cord, the role of descending GABAergic fibers in descending control is unclear.

Alterations of GABAergic activity may result in either an increase or decrease in pain sensitivity. In the insular cortex of the rat, increasing and decreasing GABA transmission produces analgesia and hyperalgesia, respectively (Jasmin, L. *et al.*, 2003b). Thus, GABAergic activity in this region appears to facilitate cortical output related to descending inhibition, which is in contrast to PAG and RVM. In the RVM, the $GABA_B$ agonist baclofen produces antinociception at low dose (0.1–1.0 ng) and hyperalgesia at high dose (30–150 ng) (Thomas, D. A. *et al.*, 1995; Hammond, D. L. *et al.*, 1998). Intrathecal methysergide antagonizes the baclofen-produced antinociception, suggesting that analgesia is related to disinhibition of bulbospinal serotonergic neurons (Hammond, D. L. *et al.*, 1998). GABAergic neurons in the DLPT also exert bidirectional pain modulation by providing tonic inhibition of two populations of noradrenergic neurons in the A7 group (Nuseir, K. and Proudfit, H. K., 2000).

Stimulation of the PAG and NRM results in release of glycine in the spinal dorsal horn and inhibition of nociceptive neuronal activity (Sorkin, L. S. *et al.*, 1993; Cui, M. *et al.*, 1999). Iontophoresis of glycine and GABA receptor agonists suppresses responses of primate spinothalamic tract neurons to noxious stimuli (Lin, Q. *et al.*, 1999). Clearly, disinhibition of glycinergic and GABAergic neurotransmission constitutes a mechanism of central sensitization and persistent pain (Cronin, J. N. *et al.*, 2004; Zeilhofer, H. U., 2005), although to what extent the descending control intervenes in this process needs to be specifically addressed. Glycine may contribute to the development of hyperalgesia via an intriguing way. As a required co-agonist for NMDA receptor activation, glycine released from inhibitory interneurons in the superficial dorsal horn can escape the synaptic cleft and access and facilitate nearby NMDA receptors through spillover (Ahmadi, S. *et al.*, 2003).

5.49.2.2.4 Others

A number of additional neurotransmitters also participate in descending pain control, although their roles are studied less extensively and a large portion of the study has focused on the different segmental levels. Some key observations are discussed below.

5.49.2.2.4.(i) Cannabinoids Endocannabinoids (endogenous marijuana-like compounds) include anandamide and 2-arachidonylglycerol, which act on two subclasses of cannabinoid receptors, CB_1 and CB_2 (Cravatt, B. F. and Lichtman, A. H., 2004; Hohmann, A. G. *et al.*, 2005). The CB1 receptors are localized in the CNS including important structures of descending pain control (Tsou, K. *et al.*, 1998). Endogenous cannabinoids produce analgesia via mechanisms apparently different from those of endogenous opioids, although they may act in similar neural circuitry involving the PAG and RVM (Walker, J. M. and Huang, S. M., 2002). Stress induces endocannabinoids in the PAG associated with analgesia that can be reversed by CB1 receptor blockade in the region (Hohmann, A. G. *et al.*, 2005). In CB_1-mutant mice, the stress-induced analgesia is selectively affected, leaving the opioid analgesia unaffected (Valverde, O. *et al.*, 2000). The analgesic effect of cannabinoids requires the RVM circuitry and cannabinoids modulate activity of RVM pain modulating neurons (Meng, I. D. *et al.*, 1998). Although generally considered to be localized peripherally, increasing evidence indicates that the CB_2 receptor in the spinal cord plays a role in the persistent pain process (Zhang, J. *et al.*, 2003).

5.49.2.2.4.(ii) Brain-derived neurotrophic factor In the adult mammalian brain, brain-derived neurotrophic factor (BDNF) facilitates excitatory synaptic transmission and long-term synaptic plasticity. Studies have shown that exogenously applied BDNF into the PAG produces analgesia in rats (Siuciak, J. A. *et al.*, 1995; Frank, L. *et al.*, 1997). Overexpression of BDNF in the spinal cord alleviates neuropathic pain (Cejas, P. J. *et al.*, 2000; Eaton, M. J. *et al.*, 2002). The analgesic effect of exogenous BDNF may be attributed to a downregulation of TrkB after a large dose of the BDNF treatment (Frank, L. *et al.*, 1997; Chen, H. and Weber, A. J., 2004). If BDNF is microinjected into the RVM at a dose within the

physiological range (10–100 fmol), pain facilitation occurs (Guo, W. *et al.*, 2006). BDNF-containing neurons in the PAG project to and release BDNF in the RVM. Intra-RVM sequestration of BDNF by TrkB–IgG fusion protein or anti-BDNF antibody and knockdown of TrkB by RNAi attenuates pain after inflammation (Guo, W. *et al.*, 2006). The effect of BDNF in the RVM is dependent on the activation of NMDA receptors. BDNF induces tyrosine phosphorylation of the NMDA receptor NR2A subunit via a signal transduction cascade that involves IP3, PKC, and Src (Guo, W. *et al.*, 2006). Thus, supraspinal BDNF–TrkB signaling contributes to net descending pain facilitation through a mechanism involving NMDA receptor activity.

5.49.2.2.4.(iii) Substance P Although substance P is a major neurotransmitter released from primary afferents at the spinal level, it is also widely distributed in supraspinal structures involved in descending pain control (Beitz, A. J., 1982a). A group of PAG neurons containing both substance P and cholecystokinin (CCK) projects to the spinal cord (Skirboll, L. *et al.*, 1983). However, the function of this descending pathway is unclear. A significant population of PAG neurons possesses neurokinin 1 (NK1) receptors, the primary binding site for substance P, and many NK1-positive PAG neurons also contain glutamate and to a lesser extent, enkephalin (Commons, K. G. and Valentino, R. J., 2002). This raises the possibility that activation of NK1 in the PAG may be upstream to glutamatergic activation and affect activity of the descending circuitry. Both pro- and antinociceptive properties have been attributed to the NK1 receptor. Holden J. E. *et al.* (2002) show that antinociception from lateral hypothalamic stimulation is mediated by NK1 receptors in the A7 cell group in rats. Suzuki R. *et al.* (2002b) demonstrate that excitation of spinal NK1-bearing projection neurons results in input to the RVM, which triggers descending pain facilitation.

5.49.2.2.4.(iv) Neurotensin Microdialysis of morphine into the ventromedial PAG induces neurotensin release (Stiller, C. O. *et al.*, 1997). The neurotensinergic input from the PAG to the RVM has been described (Beitz, A. J., 1982c). Neurotensin is involved in bidirectional descending modulation from the RVM. Microinjection of low dose (30 fmol) of neurotensin into the RVM produces hyperalgesia and facilitation of dorsal horn neuronal responses to noxious stimuli and high doses of neurotensin (0.3–3 nmol) produces antinociception (Urban, M. O. *et al.*, 1996; Urban, M. O. and Gebhart, G. F., 1997). Activation of the NT_1 receptor on spinally projecting serotonergic neurons in the RVM produces antinociception through release of serotonin in the spinal dorsal horn (Buhler, A. V. *et al.*, 2005).

5.49.2.2.4.(v) Cholecystokinin Dense immunoreactive cholecystokinin (CCK) terminals are localized to PAG and RVM neurons (Skinner, K. *et al.*, 1997). However, CCK-containing neurons in the PAG do not appear to project to the NRM (Beitz, A. J. *et al.*, 1983). Most studies agree that CCK acts as an anti-opioid peptide through CCK_2 (CCK_B) receptors (Han, J. S., 1995; Fields, H. L. and Basbaum, A. I., 1999; Veraksits, A. *et al.*, 2003). Cholecystokinin in the RVM mediates opioid-induced hyperalgesia and antinociceptive tolerance (Xie, J. Y. *et al.*, 2005). Intra-RVM pretreatment with a selective CCK_2, but not CCK_1 (CCK_A), receptor antagonist significantly potentiates the antihyperalgesic effect of morphine in a model of visceral nociception (Friedrich, A. E. and Gebhart, G. F., 2003). Supraspinal CCK may drive tonic descending facilitation mechanisms to maintain neuropathic pain in the rat (Kovelowski, C. J. *et al.*, 2000). The cellular mechanisms of the pronociceptive and anti-opioid actions of CCK involve an action on pain modulatory neurons in the RVM (Heinricher, M. M. *et al.*, 2001; Heinricher, M. M. and Neubert, M. J., 2004).

5.49.2.2.4.(vi) Acetylcholine The DLPT nuclei and RVM regions have been found to send descending cholinergic fibers to the spinal cord (Bowker, R. M. *et al.*, 1983; Jones, B. E. *et al.*, 1986). The cholinergic pedunculopontine tegmental nucleus (PPTg) in the DLPT, immediately ventral to the cuneiform nucleus, has attracted attention. The PPTg is one of the two most sensitive sites for intracranial nicotine-produced antinociception (Iwamoto, E. T., 1991). Neurons in the PPTg are responsive to noxious tail pinch (Carlson, J. D. *et al.*, 2004). Microinjection of nicotine into the NRM, the other sensitive site for the effect of nicotine, produces antinociception (Iwamoto, E. T., 1991). Intra-NRM ABT-594, a cholinergic channel modulator, produces analgesia, presumably through an action on alpha 4-containing nicotinic acetylcholine receptors coexpressed by serotonergic neurons (Bitner, R. S. *et al.*, 1998). The dorsal raphe nucleus is also a potential site for nicotinic analgesia (Cucchiaro, G. *et al.*, 2005). Spinal cholinergic receptors contribute to descending inhibition from the Gi/GiA region, although it is unclear

whether the source of acetylcholine transmitters is supraspinal (Zhuo, M. and Gebhart, G. F., 1990). At the spinal level, acetylcholine tonically modulate serotonergic transmission (Cordero-Erausquin, M. and Changeux, J. P., 2001) and both inhibitory and excitatory neurons are responsive to nicotinic stimulation (Cordero-Erausquin, M. *et al.*, 2004).

5.49.2.2.4.(vii) Histamine Central histamine is mainly derived from the tuberomammilllary nucleus of the hypothalamus and histaminergic terminals are found in the PAG, LC, RVM, and spinal cord (Millan, M. J., 2002). Among four classes of histamine receptors ($H_{1–4}$), $H_{1–3}$ receptors have been localized to the CNS but their roles in descending pain control are unclear. Activation of central H_1 receptor induces behavioral hyperalgesia in mice involving the phospholipase C–protein kinase C pathway (Galeotti, N. *et al.*, 2004). Intracerebroventricular injection of H_3 agonist is hyperalgesic in rodents (Malmberg-Aiello, P. *et al.*, 1994). However, activation of spinal histamine H_3 receptors inhibits mechanical nociception (Cannon, K. E. *et al.*, 2003). It is clear that the effects of histamine-related agents may be mediated through nonhistamine receptors. A histamine-derived compound, improgan, produces analgesia exclusively through the supraspinal circuitry involving PAG and RVM through unknown receptor mechanisms (Hough, L. B. *et al.*, 1997; Nalwalk, J. W. *et al.*, 2004).

5.49.2.2.4.(viii) Prostaglandin Recent observations suggest a role of centrally produced prostaglandins in descending pain modulation. Microinjection of prostaglandin E2 into the medial preoptic region and PAG regulates pain modulatory neurons in the RVM, the effects including activation of ON cells and suppression of OFF cells, and produces thermal hyperalgesia (Heinricher, M. M. *et al.*, 2004a; 2004b). These findings support the emerging view that the CNS glia-inflammatory cytokine network, in association with the cyclooxygenase 2-prostaglandin cascade, is involved in the development of hyperalgesia after tissue and nerve injury (Samad, T. A. *et al.*, 2001; Watkins, L. R. *et al.*, 2003). Such pathways may increase descending facilitation from the RVM circuitry and produce pain and hyperalgesia.

5.49.2.2.4.(ix) Orexins (hypocretin) The novel neuropeptides orexin A and B are selectively synthesized in the lateral and posterior hypothalamus and originally identified as a regulator of feeding behavior (Sakurai, T. *et al.*, 1998). A number of studies have suggested a role of orexin in descending pain modulation. Hypothalamic descending axons containing orexin innervate all levels of the spinal cord including superficial dorsal horn (van den Pol, A. N., 1999). Orexin A-like immunoreactive fibers in the spinal cord are mostly confined to axon terminals containing dense-cored vesicles and mainly forming asymmetric synapses (Guan, J. L. *et al.*, 2003). Initial analysis indicates that orexin-B modulates superficial dorsal horn neurons in the rat spinal cord. Orexin-B increases spontaneous inhibitory postsynaptic currents in the majority of dorsal horn neurons and also produces excitatory effects on a smaller population of dorsal horn neurons (Grudt, T. J. *et al.*, 2002). Orexins produces analgesia through central but not peripheral mechanisms and do not appear to involve the endogenous opioids (Mobarakeh, J. I. *et al.*, 2005). Activation of spinal orexin-A receptor produces antiallodynic effect in the rat with carrageenan-induced inflammation (Yamamoto, T. *et al.*, 2003). In the prepro-orexin (precursor of orexins) knockout mice, the baseline pain threshold is not altered but the knockout mice exhibit enhanced hyperalgesia after inflammation and reduced stress-induced analgesia (Watanabe, S. *et al.*, 2005). These results suggest that hypothalamic orexins and related descending pathways are activated by persistent pain and stress to produce pain inhibition.

5.49.2.2.5 Summary

The bulbospinal noradrenergic and serotonergic pathways are the most established systems with regard to descending pain modulation. The roles of other neurotransmitters and receptors in descending pain control are mainly documented at the segmental levels. The interactions between these transmitters and receptors, including receptor subtypes, are extremely extensive and sophisticated (see Chapter Pharmacological Modulation of Pain) (Millan, M. J., 2002), although their contributions are discussed individually here. A striking feature of the involvement of neurochemicals in descending pain control is that almost every substance has been shown to be involved in both inhibitory and facilitatory pain control, either through actions at the different receptor subtypes, different levels of the neuraxis, or different concentrations; and that the same transmitter may produce opposite modulatory effects at different, or even the same, segmental levels. This factor contributes to some conflicting results in this area and seriously complicates the interpretation of the

findings derived from genetic approaches that involve manipulation of specific receptor(s) at the systemic level.

5.49.2.3 Neuronal Activity in Descending Pathways

5.49.2.3.1 Pain modulatory neurons

By comparing neuronal activity to the occurrence of nociceptive reflexes in lightly anesthetized rats, Fields H. L. *et al.* (1983a) identified three classes of neurons in the RVM. One type of cell typically shows a burst of activity immediately prior to the onset of the tail flick from a noxious thermal stimulus, thus named an ON cell. Another type of cell exhibits a pause in activity just before the tail flick and is called an OFF cell. The activity of the third class of cell, NEUTRAL cell, exhibits no clear relationship to nociceptive reflexes in response to transient stimuli. The firing profiles of ON and OFF cells suggest that they are pain modulatory neurons since their activity is correlated with facilitation and inhibition of nocifensive behaviors, respectively. In fact, both RVM ON and OFF cells project to the spinal cord, particularly laminae I, II, and V of the dorsal horn (Fields, H. L. *et al.*, 1995), and are modulated by PAG stimulation and opioids (Vanegas, H. *et al.*, 1984; Fields, H. L. *et al.*, 1983b; Fields, H. L. *et al.*, 1991). Although less studied, ON and OFF cells are also found elsewhere involved in pain modulation, including the PAG (Heinricher, M. M. *et al.*, 1987), cuneiformis nucleus, PB (Haws, C. M. *et al.*, 1989) and nucleus submedius of the thalamus (Fu, J. J. *et al.*, 2002). It should be clarified that OFF-cell activity may not be solely responsible for suppressing nocifensive withdrawals. In the unanesthetized rat during slow wave sleep, animals are able to execute withdrawal from noxious stimulation when OFF cell continues to fire (Leung, C. G. and Mason, P., 1999). Simultaneous recordings from spinal and RVM neurons show that ON- and OFF-cell firing reflects well input from the spinal dorsal horn, suggesting a role in gating ascending nociceptive information (Hernandez, N. *et al.*, 1989; Hernandez, N. and Vanegas, H., 2001). In addition to regulation of nocifensive responses, ON- and OFF-cell activity may also play a role in integrating cardiovascular, visceral, and somatosensory input (Thurston, C. L. and Randich, A., 1995) and regulating homeostatic functions (Mason, P., 2001).

In vitro recordings from medullary slices identified two distinct cell types in the NRM, primary and secondary cells (Pan, Z. Z. *et al.*, 1990). Primary cells exhibit large GABA-mediated synaptic potentials and are insensitive to opioids, while secondary cells have little or no GABAergic input and are hyperpolarized by opioids. Primary and secondary are likely corresponding to OFF and ON cells, respectively, based on their pharmacological characteristics, such that local iontophoretic of morphine directly inhibits ON cells but does not affect OFF cells (Fields, H. L. and Basbaum, A. I., 1999). Excitatory amino acid transmission is involved in modulating both ON and OFF cell activity (Heinricher, M. M. *et al.*, 1999), which is in line with the evidence that both primary and secondary cell types receive excitatory amino acid input. Models have been proposed to understand the functional significance of neuronal activity within the RVM circuitry. In the disinhibition model, opioids directly inhibit ON cells (corresponding to secondary cells) and release the GABAergic inhibition of OFF cells (corresponding to primary cells), resulting in pain inhibition (Fields, H. L. and Basbaum, A. I., 1999). RVM neurons are also subject to modulation by noradrenergic input (Hammond, D. L. *et al.*, 1980), which mainly originated from the DLPT nuclei (Tanaka, M. *et al.*, 1996; Meng, X. W. *et al.*, 1997). Opposite to the spinal cord, activation of alpha 2 adrenoceptors hyperpolarizes primary cells and attenuates opioid analgesia, and activation of alpha 1 adrenoceptors depolarizes primary cells and enhances analgesia (Bie, B. *et al.*, 2003).

The finding of ON and OFF cells provides a cellular mechanism for bidirectional descending pain control and favors our understanding of variability of pain (Fields, H. L., 1988). It should be emphasized that the descending facilitation parallels inhibition and is an active process. The enhanced nociceptive responsiveness in morphine-dependent rats after treatment with opioid receptor antagonists is accompanied by an increased RVM ON-cell firing (Bederson, J. B. *et al.*, 1990). In spite of a well-documented RVM–spinal serotonergic projection in descending pain control, Gao K. and Mason P. (2000) found that serotonergic RVM cells that respond to noxious tail heat are not ON or OFF cells. The transmitters released by axon terminals of RVM ON and OFF cells in the spinal cord remain to be verified.

Pan Z. Z. *et al.* (1997) show that activation of the kappa-receptor hyperpolarizes primary cells that are disinhibited through the inhibition of secondary cells by mu-opioid receptors. Thus, mu- and kappa-opioid receptors may produce opposing actions on RVM pain modulatory neurons. This kappa effect reverses the analgesic effect of mu-opioids (Bie, B. and Pan, Z. Z.,

2003). Activation of the kappa-opioid receptor in the RVM has also been shown to produce antinociception in a test modality-dependent manner. Microinjection of a kappa-receptor agonist U69593 into the RVM increased withdrawal latency of paw, but not the tail, to noxious thermal stimulus (Ackley, M. A. *et al.*, 2001). The opioid withdrawal-induced hyperalgesia is attenuated by intra-RVM kappa-agonist (Bie, B. and Pan, Z. Z., 2003). The cellular mechanisms of these differential actions of the kappa-opioid on RVM neurons and behavioral nociception are unclear and appear to involve a presynaptic inhibition of glutamatergic input to pain modulatory neurons (Ackley, M. A. *et al.*, 2001; Bie, B. and Pan, Z. Z., 2003) (also see Chapter The Brainstem and Nociceptive Modulation).

5.49.2.3.2 Descending influence on dorsal horn neurons

5.49.2.3.2.(i) Tonic effect Wall P. D. (1967) originally observed that blocking impulses descending from the brainstem induced an increased activity of laminae IV/V dorsal horn neurons in the cat. In contrast, the response of lamina VI neurons to movement was mainly reduced. This suggests a tonic brainstem descending inhibition on cutaneous sensory processing in the dorsal horn and a facilitatory control over proprioceptive activity. The tonic inhibition of dorsal horn neurons is confirmed by later studies (Besson, J. M. *et al.*, 1975; Cervero, F. *et al.*, 1976; Dickhaus, H. *et al.*, 1985; Ren, K. and Dubner, R., 1996).

It is worth noting that if a portion of the descending pathways is blocked or only NRM is anesthetized, dorsal horn nociceptive neurons do not show an increased activity (Cervero, F. *et al.*, 1979; Gebhart, G. F. *et al.*, 1983). Apparently, tonic suppression of dorsal horn activity is implemented by multiple descending pathways or supraspinal sites; and the loss of inhibition from one pathway can be compensated by others.

The findings of Wall also reveal the plastic nature of dorsal horn neurons. In lamina IV, many low threshold neurons became wide dynamic range neurons; and in lamina V, the receptive fields of nociceptive neurons were expanded during the spinal cord block. Collins J. G. and Ren K. (1987) showed that, after a low dose of pentobarbital in the intact awake cat, dorsal horn neurons (originally only responsive to noxious stimuli) became responsive to low-intensity stimuli, that is, the wide dynamic range response profile is unmasked. This effect is likely due to a release of inhibitory systems that regulate spinal dorsal horn activity, consistent with Wall's hypothesis (Wall, P. D., 1967).

5.49.2.3.2.(ii) Inhibitory effect Descending input produces inhibition of dorsal horn neurons through multiple synaptic mechanisms (Light, A. R. *et al.*, 1986; Zhang, D. X. *et al.*, 1991; Fields, H. L. and Basbaum, A. I., 1999). As spinal serotonin and noradrenaline are almost exclusively of supraspinal origin, they provide postsynaptic control of spinal neurons. Westlund K. N. *et al.* (1990) demonstrated that spinothalamic neurons in primate receive direct catecholaminergic innervation. Stimulation of the NRM produces direct postsynaptic inhibition of spinothalamic tract neurons (Giesler, G. J. Jr. *et al.*, 1981). Descending input can also modulate secondary order neurons indirectly through action on interneurons. NRM and spinal stimulation increases glycine and GABA release into the spinal cord, suggesting activation of inhibitory interneurons (Sorkin, L. S. *et al.*, 1993; Cui, J. G. *et al.*, 1997). Since changes in activity of interneurons can lead to changes in presynaptic inhibition related to primary afferent depolarization, primary afferent fibers are also indirectly modulated by descending input (Martin, R. F. *et al.*, 1979).

5.49.2.3.2.(iii) Facilitatory effect Supraspinal structures also exert facilitatory influences on spinal nociceptive transmission. Tattersall J. E. *et al.* (1986) report that 44% of neurons recorded from the lower thoracic spinal cord of the cat show reduced response to visceral stimulation after reversible spinalization, suggesting that they are under descending excitatory control. Excitation and inhibition of dorsal horn neurons are produced by stimulation of the DLF of the spinal cord (Dubuisson, D. and Wall, P. D., 1979; McMahon, S. B. and Wall, P. D., 1988), NRM (Dubuisson, D. and Wall, P. D., 1980), and Gi (Haber, L. H. *et al.*, 1980). Even microinjection of morphine into the NRM produces facilitation of C-fiber responses of some dorsal horn nociceptive neurons (Le Bars, D. *et al.*, 1980). Although in most cases, it is unclear whether facilitation occurs on inhibitory interneurons, excitation of which may result in subsequent inhibition, Haber L. H. *et al.* (1980) demonstrate the Gi stimulation-produced excitation of primate spinothalamic tract neurons, indicating descending facilitation of nociceptive transmission. Several studies suggest a spinal–brainstem loop in the modulation of spinal pain processing. The activity of this loop involves descending inhibition or facilitation of dorsal horn neurons (Cervero, F.

and Wolstencroft, J. H., 1984; McMahon, S. B. and Wall, P. D., 1988; Suzuki, R. *et al.*, 2002b). Spinal 5-HT_3 receptors mediate descending facilitation of deep dorsal horn neurons, which involves a circuitry consisting of ascending NK1-expressing neurons in the superficial dorsal horn and descending fibers from RVM (Suzuki, R. *et al.*, 2002b).

5.49.2.4 Multiplicity of Descending Control

The bidirectional descending modulation of nociception has now been appreciated. It appears that some sites in the rostral medulla play an essential role in this balanced descending modulation. Depending on the intensities used and the specific site, stimulation of the Gi and RVM regions produces facilitation (5–25 μA) and inhibition (50–200 μA) of nocifensive reflexes and dorsal horn nociceptive neurons (Zhuo, M. and Gebhart, G. F., 1992; 1997). RVM neurons may exert bidirectional control of nociception through descending serotonergic pathways (Zhuo, M. and Gebhart, G. F., 1991) as well as via the A7 catecholamine cell group. Enkephalin-containing neurons in the RVM project to the A7 cell group and microinjection of morphine in the A7 cell group produces facilitation and inhibition of spinal nociception mediated by alpha 1- and alpha 2-adrenoceptors (Holden, J. E. *et al.*, 1999). The other site that is involved in descending facilitation is the subnucleus reticularid dorsalis (SRD) of the caudal medulla (Lima, D. and Almeida, A., 2002). Lesioning the SRD depresses nociceptive responses to acute and inflammatory pain, whereas stimulation produces pain facilitation. The SRD-mediated facilitation requires a reciprocal disynaptic putative excitatory circuit that links the SRD and the spinal dorsal horn. It is interesting that both facilitatory and inhibitory pathways can be triggered by activation of visceral afferents. Under certain circumstances, vagal afferent stimulation at relative low intensities produces facilitation of the nociceptive tail flick reflex as well as dorsal horn nociceptive neuronal activity (Randich, A. and Gebhart, G. F., 1992). The neural relays involved in vagal afferent-produced facilitation and inhibition also include sites within the RVM. Thus, spinal nociceptive processing is subject to bidirectional control from supraspinal sites so that the intensity of perceived pain can be fine-tuned by descending pathways.

In general, when biphasic pain modulation is observed at the same site, facilitation is produced by electrical stimulation given at lesser intensities or receptor agents administered at lower doses and inhibition is found at higher intensities of stimulation or larger doses of the receptor agents, with few exceptions (Thomas, D. A. *et al.*, 1995; Hammond, D. L. *et al.*, 1998). This may explain why descending facilitation was not recognized in many earlier reports because the facilitation might often be masked by more intense electrical stimulation or higher drug doses used to produce net descending inhibition. It remains to be explained how and why a manipulation at the same site by varying stimulation intensities would produce opposing effects on nociceptive transmission. Pain modulating neurons of different modalities intermingle with each other within the RVM and the membrane properties of ON and OFF cells are very similar (Zagon, A. *et al.*, 1997). One can only speculate that the net effect of excitation of brainstem nuclei is related to differential activation of subsets of neurons with different connections and different combinations of neurotransmitter receptors. In the case of BDNF, brain microinjection at a dose within the normal range, determined by measuring its concentration *in vivo*, produces nociceptive facilitation (Guo, W. *et al.*, 2006), but higher doses lead to antinociception (Siuciak, J. A. *et al.*, 1995; Frank, L. *et al.*, 1997; Guo, W. *et al.*, 2006). This suggests that activation of BDNFergic transmission at the physiological level results in facilitation and inhibition produced by larger doses may result from the recruitment of excessive synapses that are not normally active simultaneously. We should also be aware that supraspinal descending influences might exert differential effects on motor reflex and dorsal horn neuronal activity that are used by most animal studies as the endpoints (Willer, J. C. *et al.*, 1979). Future studies should validate pain facilitation and inhibition by including the affective component of pain and not merely measure reflex behaviors (Vierck, C. J. Jr. *et al.*, 2004; Neubert, J. K. *et al.*, 2005).

5.49.3 Plasticity of Descending Pathways

To be able to feel pain is a normal and essential function for living. Pain warns the body against injury and illness so that responses will be undertaken to protect the body. Normally, pain goes away when the damage is resolved and tissues are healed, and will not be long-lasting. However, chronic pain develops under a variety of conditions even without the

presence of injury, and the suffering from excessive persistent pain has been a major health problem. Most earlier studies on the descending pain control mechanisms have focused on responses to acute or transient noxious stimuli, which has built up the fundamentals for our understanding of the system. Recent studies have turned attention to chronic pain conditions and examined the effects of pain that last for hours, days, or longer, following tissue damage or nerve injury. Persistent pain conditions are associated with prolonged functional changes in the nervous system, evidenced by the development of dorsal horn hyperexcitability, or activity-dependent plasticity, also commonly referred to as central sensitization. Evidence has accumulated to indicate that descending pathways also exhibit plasticity that contributes to altered pain processing after injury (Porreca, F. *et al.*, 2002; Ren, K. and Dubner, R., 2002; Vanegas, H. and Schaible, H.-G., 2004).

5.49.3.1 Descending Modulation in Persistent Pain

5.49.3.1.1 Responses of descending pathways to injury

In the rat inflammation model, intraplantar injection of carrageenan induces inflammation and hyperalgesia that is associated with an increased Fos protein expression, a marker of neuronal activation, in the PB and LC/SC (Bellavance, L. L. and Beitz, A. J., 1996; Buritova, J. *et al.*, 1998; Tsuruoka, M. *et al.*, 2003). In adjuvant-induced inflammation and the sciatic nerve ligation model, there is a selective increase in proneurotensin mRNA expression in the PAG (Williams, F. G. and Beitz, A. J., 1993). In contrast, veratridine-induced GABA release is decreased in the PAG after hind paw inflammation (Renno, W. M. and Beitz, A. J., 1999). Orofacial inflammation activates the coeruleotrigeminal antinociceptive pathway (Matsutani, K. *et al.*, 2003) and hind paw inflammation induces an increase in NA levels in the spinal dorsal horn, suggesting activation of descending noradrenergic pathways (Tsuruoka, M. *et al.*, 1999).

In rats receiving chronic constriction injury of the sciatic nerve (the CCI model), in addition to the sensory structures of the cortex and thalamus, changes in brain neural activity are observed in a variety of regions involved in descending control including the hypothalamic arcuate nucleus and central gray matter, LC, PB, and Gi (Mao, J. *et al.*, 1993). The activation of GiA-mediated descending pain inhibition is shown in rats with partial sciatic nerve ligation (Azami, J. *et al.*, 2001). In the CCI model, there is an upregulation of spinal CB_1 receptors and an increased antihyperalgesic and antiallodynic effect of Win 55,212-2, a CB receptor agonist (Lim, G. *et al.*, 2003), although it is unclear whether descending input contributes to this enhanced pain inhibition.

Intraplantar injection of formalin has been used extensively as a model of prolonged chemical nociception. In rats receiving formalin injection, there is an increase in noradrenaline and serotonin concentrations in the spinal dorsal horn. Intrathecal pretreatment with yohimbine, an alpha 2 adrenoceptor antagonist, and methysergide, a 5-HT receptor antagonist, significantly enhanced nocifensive behavior (Omote, K. *et al.*, 1998). These results suggest activation of descending monoaminergic pathways by formalin. In the PAG, formalin injection leads to a decrease in GABA release (Maione, S. *et al.*, 1999). A decreased GABAergic tone in the PAG presumably will disinhibit PAG neurons and result in activation of opioid interneurons in the RVM, leading to increased descending inhibition.

In humans with secondary hyperalgesia after heat/capsaicine sensitization, the PAG and the cuneiform nucleus activation is observed using whole-brain functional magnetic resonance imaging (Zambreanu, L. *et al.*, 2005). These multiple lines of evidence indicate that, not only can stimulation of pain modulatory circuitry attenuate hyperalgesia and dorsal horn neuronal hyperexcitability after inflammation and nerve injury (Morgan, M. M. *et al.*, 1991; Sotgui, M. L., 1993), descending pathways are also activated under persistent pain conditions.

5.49.3.1.2 Descending inhibition in persistent pain

There is now considerable evidence that inflammatory injury induces an enhanced net descending inhibition at sites of primary hyperalgesia (Ren, K. and Dubner, R., 2002). In cats with knee joint inflammation, descending inhibition is greater in neurons with input from the inflamed knee as revealed by reversible spinalization with a cold block and DNIC-induced inhibition (Schaible H. G. *et al.*, 1991; Danziger, N. *et al.*, 1999; 2001). Similar phenomenon is observed in rats with adjuvant-induced hind paw inflammation. Local anesthetic block of the thoracic spinal cord leads to an increased activity of dorsal horn nociceptive neurons that is greater in inflamed than that in noninflamed rats (Ren, K. and Dubner, R.,

1996). Studies using Fos protein expression as a marker of neuronal activation have reached a similar conclusion. There are more inflammation-induced Fos-expressing neurons in the spinal dorsal horn in spinally transected or DLF-lesioned rats, when compared to sham-operated inflamed rats (Ren, K. and Dubner, R., 2002). Kauppila P. *et al.* (1998) show that thermal but not mechanical nociceptive responses are further enhanced in hind paw-inflamed and spinal nerve-ligated rats after spinalization at the midthoracic level. Furthermore, behavioral hyperalgesia is intensified in rats with lesions of the dorsal lateral quadrant of the spinal cord after inflammation or formalin injection (Abbott, F. V. *et al.*, 1996; Ren, K. and Dubner, R., 1996). These studies reveal the net descending inhibitory effects after tissue injury. The enhanced descending net inhibition serves to dampen injury-induced dorsal horn hyperexcitability and hyperalgesia.

The source of the enhanced inhibition can be traced back to brainstem structures. Local anesthesia of the RVM results in a further increase in dorsal horn nociceptive neuronal activity in hind paw-inflamed rats (Ren, K. and Dubner, R., 1996). Focal lesions of the RVM and LC are followed by an increase in spinal Fos expression and hyperalgesia after inflammation (Tsuruoka, M. and Willis, W. D., 1996; Wei, F. *et al.*, 1999). When lidocaine was microinjected into the NRM in adjuvant-inflamed rats, increases in activity were observed in over 75% of the spinal dorsal horn neurons (Ren, K. and Dubner, R., 1996). Interestingly, there appears to be laminar selectivity in the effect of RVM serotoninergic and LC noradrenergic descending pathways. The descending serotoninergic and noradrenergic pathways differentially suppress the responses of spinal neurons, including spinoparabrachial neurons, in the deep and superficial dorsal horn, respectively (Ren, K. *et al.*, 2000). It appears that both RVM and LC descending pathways are major sources of enhanced net inhibition in inflamed animals.

5.49.3.1.3 Descending facilitation in persistent pain

Descending input also exerts a facilitatory effect following injury. Emerging evidence indicates that descending facilitation not only parallels inhibition but also can be a driving force for the development of persistent pain (Porreca, F. *et al.*, 2002; see Figure 3). The selective destruction of the Gi with a soma-selective neurotoxin, ibotenic acid, leads to an attenuation of hyperalgesia and a reduction of

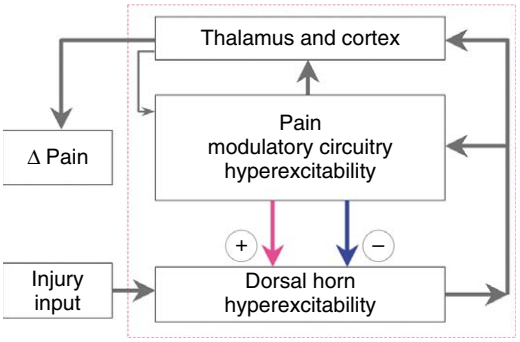

Figure 3 Diagram illustrating descending pain facilitation and inhibition in persistent pain. An enhanced primary afferent input after injury may lead to dorsal horn hyperexcitability and produce dynamic changes in excitability within brain stem pain modulatory circuitry. The net effect of descending modulation depends on a balance between inhibitory (−) and facilitatory (+) input to the spinal cord. An increase in descending net facilitatory modulation may lead to the development of persistent pain. Adapted from Ren, K., Zhuo, M., and Willis, W. D. 2000. Multiplicity and Plasticity of Descending Modulation of Nociception: Implications for Persistent Pain. In: Proceedings of the 9th World Congress on Pain (*eds*. M. Devor, M. C. Rowbotham, and Z. Wiesenfeld-Hallin), pp. 387–400. IASP Press.

inflammation-induced spinal Fos expression (Wei, F. *et al.*, 1999). The descending facilitatory effect may also originate from the medullary SRD (Lima, D. and Almeida, A., 2002) and other brain sites such as the anterior cingulate cortex (Calejesan, A. A. *et al.*, 2000).

Descending facilitation significantly contributes to the deveolpment of certain types of persistent pain, particularly those associated with secondary hyperalgesia or nerve injury. Spinalization blocks mustard oil-produced secondary allodynia and hyperexcitability of dorsal horn neurons (Mansikka, H. and Pertovaara, A., 1997). RVM lesions prevent formalin-induced nocifensive behavior (Wiertelak, E. P. *et al.*, 1997) and inhibit secondary hyperalgesia produced by topical application of mustard oil (Urban, M. O. and Gebhart, G. F., 1999). Masseter muscle inflammation produces mechanical hyperalgesia of the overlying skin that is blocked by RVM lesions, and likely includes secondary hyperalgesia of the skin and primary hyperalgesia of the muscle (Sugiyo, S. *et al.*, 2005). The same phenomenon occurs in models of neuropathic pain. Suzuki R. *et al.* (2004a) show that descending facilitatory control of mechanically evoked responses is enhanced in dorsal horn neurones after nerve injury. Local anesthesia of the PAG or RVM attenuates allodynia in rats receiving

ligation of the two spinal nerves (Pertovaara, A. *et al.*, 1996; Kovelowski, C. J. *et al.*, 2000). The tactile allodynia and cold hypersensitivity after nerve injury depends upon activation of bulbospinal descending facilitatory pathways (Ossipov, M. H. *et al.*, 2000; Urban, M. O. *et al.*, 2003). Microinjection of the CCK_2 receptor antagonist L365,260 into the RVM reverses tactile allodynia and thermal hyperalgesia after L5/L6 spinal nerve ligation and intra-RVM CCK-8 produces allodynia and hyperalgesia (Kovelowski, C. J. *et al.*, 2000). These findings indicate that CCK may drive descending facilitation to maintain neuropathic pain in rats, which is consistent with the anti-opioid action of CCK in RVM. In nerve-injured rats, lesions of the DLF, local anesthetic block of the RVM, and lesions of RVM mu-opioid receptor expressing cells do not prevent the onset, but reverse the later maintenance of tactile and thermal hypersensitivity (Porreca, F. *et al.*, 2001; Burgess, S. E. *et al.*, 2002). These observations point to an ascending–descending loop that is activated in response to prolonged stimulation to facilitate spinal nociceptive processing. The ascending dorsal column pathways likely contribute to this pain facilitatory circuitry in neuropathic pain models (Miki, K. *et al.*, 2000). There is no evidence of activation of the dorsal column pathway in models of inflammatory primary and secondary hyperalgesia.

5.49.3.1.4 Descending facilitation versus inhibition

Clearly, descending modulation of persistent pain involves both inhibition and facilitation. Although there may exist selective circuitry that is responsible for multiple phases of modulation, it is rather surprising that the facilitatory sites in the rostral medulla generally overlap with the sites that also produce inhibition. The inhibition and facilitation may also share some synaptic mechanisms with subtle difference in sensitivity. Although many of the above cited studies have concluded that the hyperalgesia is dependent completely on facilitatory influences from the brainstem, it should be noted that the same effects could be produced by a reduction in descending inhibition leading to a dominance of descending facilitation. The serotonin concentration in the NRM is reduced in mice with diabetic neuropathy and sciatic nerve ligation, which is associated with a reduced opioid analgesia (Sounvoravong, S. *et al.*, 2004). Thus, neuropathic hyperalgesia may be dependent on a net descending facilitatory effect wherein a simultaneous descending inhibition is dominated by the facilitation. After tissue or nerve injury, there is an increase in synaptic strength for both descending inhibition and facilitation. Both facilitatory and inhibitory circuitry may be activated by ascending input after injury (Herrero, J. F. and Cervero, F., 1996; Gozariu, M. *et al.*, 1998). There is an increase in ON- and OFF-cell activity after inflammation (Miki, K. *et al.*, 2002). Thus, the balance between synaptic excitation and inhibition under different conditions appears important. The Gi plays a role in descending facilitation of nociceptive transmission after transient noxious stimuli (Zhuo, M. and Gebhart, G. F., 1992). Lesions of the Gi produce an attenuation of hyperalgesia and spinal Fos expression after inflammation (Wei, F. *et al.*, 1999). However, combined Gi and NRM lesions reverse the opposite Gi or NRM lesion-induced effects. It is possible that severe persistent pain may be enhanced when the facilitatory network overrides the inhibition. In cases of neuropathic pain and secondary hyperalgesia, descending facilitation provides a driving force for the maintenance of persistent pain (also see Chapter Neuropathic Pain: Basic Mechanisms (Animal)).

5.49.3.2 Dynamics of Descending Pain Modulation

5.49.3.2.1 Time-dependent shift in descending control

There is a gradual build-up of descending inhibition in the early phase of tissue inflammation (Schaible, H. G. *et al.*, 1991; Ren, K. and Dubner, R., 1996; Hurley, R. W. and Hammond, D. L., 2000). The difference in inflammation-induced Fos expression between transected and sham controls is clear at 3 days but not apparent shortly (2 h) after inflammation (Ren, K. and Ruda, M. A., 1996). In early stages of inflammation, the dynamic response is similar in both the spinally intact and transected rats, suggesting that descending inhibitory inputs play less of a role in the early response to peripheral inflammation. In contrast, at 3 days after inflammation, descending inhibition is enhanced to counteract continuous noxious input. The results from electrophysiological studies also suggest a progressive enhancement of descending inhibition of dorsal horn neurons during the development of inflammation (Schaible, H. G. *et al.*, 1991). An effect of Freund's adjuvant on the contralateral spinal cord may also be subject to the inhibitory control of descending inputs as suggested by a clear contralateral increase in Fos-positive cells

in transected rats after inflammation (Ren, K. and Ruda, M. A., 1996). Williams F. G. and Beitz A. J. (1993) demonstrate that after peripheral inflammation or nerve injury, the increase in neurotensin mRNA expression was confined to the ventromedial PAG and the dorsal raphe nucleus initially and spreads to the structures neighboring the PAG including the cuneiform nucleus and the PPTg as the injury persists. The enhanced descending inhibition in inflamed animals has been shown to subside in the late stage at 2 weeks (Guan, Y. *et al.*, 2003). In the ankle monoarthritis rat model, tonic descending inhibition of convergent neurons with input from the inflamed ankle was enhanced during the acute stage (1–2 d) and then decreased in the chronic stage (3–4 weeks) of monoarthritis (Danziger, N. *et al.*, 1999; 2001).

The dynamic changes in descending inhibition after inflammation can be examined over time by monitoring antinocifensive responses in lightly anesthetized rats during RVM stimulation (Figure 4). Terayama R. *et al.* (2000) directly compared the potency of descending inhibition during the development of inflammation in the lightly anesthetized rat preparation. Following a unilateral hind paw inflammation, the stimulus-response function (S-R) curve for the inflamed paw was initially shifted to the right of the noninflamed paw at 3 h and then gradually shifted to the left and reached the maximal potency at 24 h after inflammation (Figure 4(b)). These findings indicate that inflammation induces dramatic changes in the excitability of RVM pain-modulating circuitry. Early (up to 3 h) in the development of inflammation there is an increased descending facilitation also shown by Urban M. O. and Gebhart G. F. (1999), which reduces the net effect of the inhibition. Over time, the level of descending inhibition increases, or descending facilitation decreases, leading to a net enhancement of antinocifensive behavior. Direct stimulation of the DLF that bypasses brainstem synaptic mechanisms does not produce a change in excitability, indicating that the changes are due to supraspinal mechanisms at the level of the RVM or higher.

Thus the activity of descending pathways exhibits considerable plasticity. Brainstem descending pathways become progressively more involved in suppressing incoming nociceptive signals in primary hyperalgesic zones following inflammation. Injury-related, persistent primary afferent input is most likely responsible for triggering this ascending–descending feedback circuit.

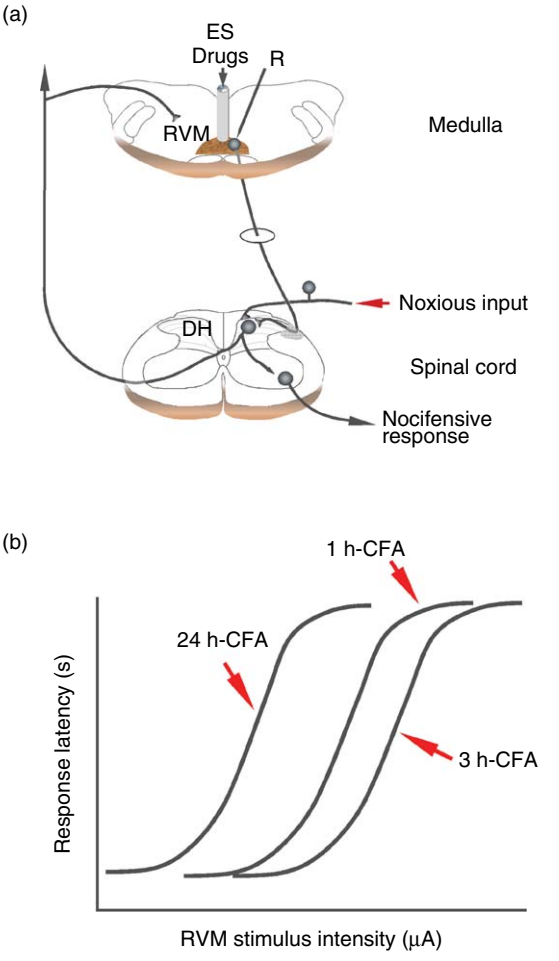

Figure 4 Time- and stimulus intensity-dependent changes in RVM electrical stimulation-produced suppression of nocifensive responses. (a) Schematic representation of the experimental setup. In lightly anesthetized animals, nocifensive responses such as paw withdrawal can be evoked by noxious stimulus. Electrical stimulation (ES) or drugs can be delivered through a guide cannula placed in the RVM. Neuronal activity can be recorded (R) in this preparation (see Figure 5). (b) The nocifensive response latency is plotted against the RVM ES intensity. The stimulus-response function (S-R) curve illustrates intensity-dependent inhibition of nocifensive responses, as indicated by an increase in response latency. Animals were inflamed with complete Freund's adjuvant (CFA), an inflammatory agent. The S-R curve at 1 h post-CFA is located in the middle. At 3 h post-CFA, the curve shifted to the right, suggesting a decrease in descending inhibition at this time. At 24 h post-CFA, the S-R curve shifted to the left, suggesting an enhanced descending inhibition. These results demonstrate dynamic changes in descending pain control during the development of inflammatory hyperalgesia. Adapted from Terayama, R., Guan, Y., Dubner, R., and Ren, K. 2000. Activity-induced plasticity in brain stem pain modulatory circuitry after inflammation. Neuroreport 11, 1915–1919.

5.49.3.2.2 Phenotypic changes in pain modulatory neurons

The time-dependent plasticity in descending pain modulatory circuitry involves changes in the response profiles of RVM neurons. Montagne-Clavel J. and Oliveras J. L. (1994) have shown changes in RVM neuronal properties after inflammation in the awake, freely moving rat, which suggests an increase in the population of neurons involved in pain modulatory activity. Using paw withdrawal as a behavioral correlate to assess the relationship between nocifensive behavior and RVM neural activity, ON-, OFF-, and NEUTRAL-like cells can be identified (Miki, K. *et al.*, 2002). Interestingly, some NEUTRAL-like cells change their response profile and can be reclassified as ON- or OFF-like cells through continuous recordings during the development of inflammation (Figure 5). These findings suggest that NEUTRAL cells have potential to become involved in pain modulation after injury. Another study by Schnell C. *et al.* (2002) shows that rat RVM neurons may display different properties depending on the site of peripheral stimulation. A NEUTRAL cell responds in an ON or OFF fashion to stimuli applied to the craniofacial region, although it is nonresponsive to noxious stimulation of the tail.

The switch in the response profile of RVM neurons correlates with the temporal changes in excitability in the RVM after inflammation. This phenotypic change of RVM neurons is verified in a population study that shows a significant increase in the percentage of ON- and OFF-like cells, and a decrease in the NEUTRAL-like cell population 24 h after inflammation as compared to control animals (Miki, K. *et al.*, 2002). The studies of RVM neurons support the view that enhanced descending modulation after inflammation involves both facilitation and inhibition since there are changes in the responses of both ON and OFF cells (Miki, K. *et al.*, 2002; de Novellis, V. *et al.*, 2005). After inflammation, there is a greater increase in ON-like cell responses before the onset of paw withdrawal as compared to that in naïve controls. ON-cell activity is associated with facilitation of nocifensive behavior (Fields, H. L. and Basbaum, A. I., 1999). In contrast, OFF-like cell responses are reduced after inflammation indicated

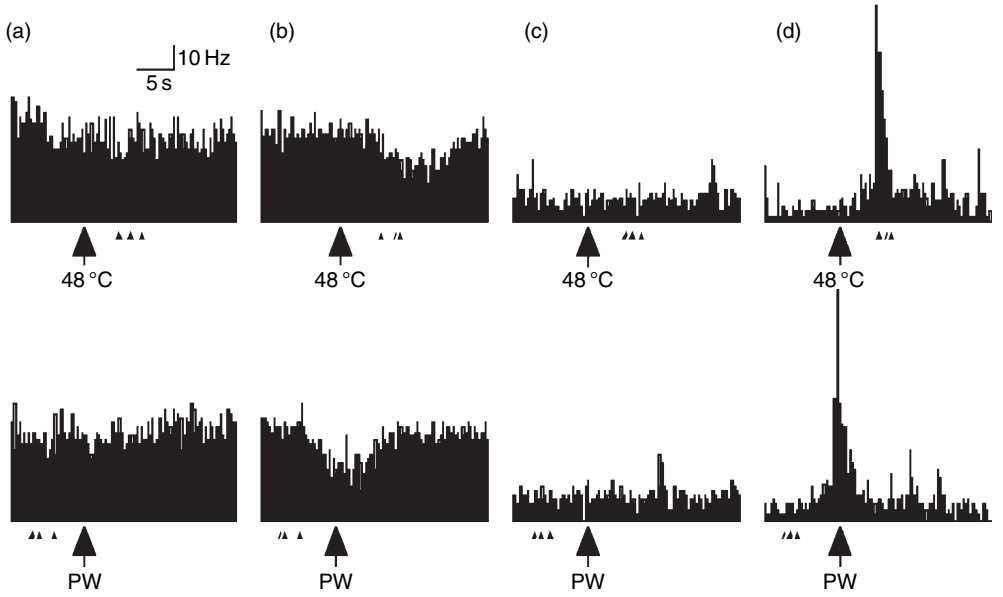

Figure 5 Examples of phenotypic changes of RVM neurons following inflammation. (a) Neutral-like cell, 9 h post-CFA. (b) Panels illustrate that at 14.5 h post-CFA, the same neuron shown in A exhibited a reduction of activity immediately before the paw withdrawal, characteristic of an OFF-like cell. (c) Neutral-like cell, 2 h post-CFA. (d) The same cell shown in (c) became an ON-like cell at 5.5 h post-CFA when the cell showed a burst of activity immediately before the paw withdrawal. All histograms were averaged from three repeated trials (200 ms bin width). The histograms are time-locked to the thermal stimuli (upper row) or the onset of paw withdrawal (lower row), respectively. Small arrowheads indicate the onset of paw withdrawal s (upper row) or onset of thermal stimuli (48 °C, lower row) for individual trials, respectively. Note that the changes in neuronal activity are best correlated with the paw withdrawal response. Adapted from Miki, K., Zhou, Q. Q., Guo, W., Guan, Y., Terayama, R., Dubner, R., and Ren, K. 2002. Changes in gene expression and neuronal phenotype in brain stem pain modulatory circuitry after inflammation. J. Neurophysiol. 87, 750–760.

by a less reduction in neuronal activity after the noxious stimulus, and a lack of a complete pause. The pause in OFF-cell activity is associated with disinhibition; the lack of the pause and the less reduction in neuronal activity suggest an increased inhibition of nocifensive behavior.

5.49.3.2.3 Involvement of excitatory amino acids and receptors

What are the cellular mechanisms that underlie these changes? Excitatory amino acids (EAAs) have been shown to mediate descending modulation in response to transient noxious stimulation and early inflammation (Urban, M. O. and Gebhart, G. F., 1999; Heinricher, M. M. *et al.*, 1999), and they are involved in the development of RVM excitability associated with inflammatory hyperalgesia (Terayama, R. *et al.*, 2000; Guan, Y. *et al.*, 2002; Miki, K. *et al.*, 2002). Microinjection of NMDA into the RVM produces effects that are dependent upon the postinflammatory time period. At 3 h post inflammation, low doses of NMDA produce facilitation of the response to noxious heat of the inflamed hind paw and the noninflamed hind paw and tail, supporting findings that descending facilitatory effects are NMDA receptor dependent and occur early after inflammation (Urban, M. O. and Gebhart, G. F., 1999). Higher doses of NMDA at 3 h post inflammation only produce inhibition. At 24 h post inflammation, NMDA produces only inhibition. All of these effects are blocked by administration of NMDA receptor antagonists. AMPA, a selective AMPA receptor agonist, produces dose- and time-dependent inhibition that is significantly greater at 24 h compared to that at 3 h post inflammation. There is a leftward shift of the dose-response curves of NMDA- and AMPA-produced inhibition at 24 h post inflammation as compared to 3 h. The leftward shift of the dose-response curves of EAA receptor agonists parallels the time-dependent enhancement of net descending inhibition produced by RVM electrical stimulation, which is also attenuated by NMDA receptor antagonists (Terayama, R. *et al.*, 2000). These results suggest that the enhanced EAA neurotransmission contributes to the time-dependent functional changes in descending modulation.

5.49.3.2.4 Molecular mechanisms of activity-dependent plasticity in descending pathways

Correlate changes in gene transcription and protein translation have been found in the descending circuitry after injury. Williams F. G. and Beitz A. J. (1993) show that adjuvant-induced hindpaw inflammation increased neurotensin mRNA expression in the PAG and the lateral tegmental nuclei, from which neurotensinergic neurons project to the RVM. The increased sensitivity of EAA receptors in the descending circuitry during the development of inflammatory hyperalgesia is related to transcriptional and translational modulation of the receptors (Ren, K. and Dubner, R., 2002). Examination of the mRNA expression of the NR1, NR2A, and NR2B subunits of the NMDA receptor in the RVM reveals an upregulation that parallels the time course of the RVM excitability changes. This is accompanied by an increase in NMDA receptor protein. Protein phosphorylation is a major mechanism for regulation of receptor function. The native NMDA receptor is likely a tetramer that consists of two NR1 and two NR2 subunits. Phosphorylation of multiple sites in the cytoplasmic C-termini of the NR1 and NR2 subunits, including tyrosine, serine, and threonine residues, is known to modulate NMDA receptor activity and affect synaptic transmission. There was an increase in NR2A, but not NR2B, tyrosine phosphorylation in the RVM after inflammation (Guo, W. *et al.*, 2006). In contrast, inflammation induces an increase in NR2B, but not NR2A subunit tyrosine phosphorylation in the spinal cord. A time-dependent increase in NR1 serine phosphorylation has also been identified in the RVM after inflammation.

There is also an increase in the AMPA receptor GluR1 subunit levels in the RVM post inflammation (Guan, Y. *et al.*, 2003). AMPA receptor subunits (GluR1–4) exist in the two flip and flop isoforms that differentially affect the desensitization properties of the receptor. Reverse transcription polymerase chain reaction analysis indicates that inflammation induces a significant upregulation of mRNAs encoding the GluR1-flip (5–24 h post inflammation), GluR2-flip (24 h post inflammation) and GluR2-flop (24 h post inflammation) isoforms in the RVM, whereas the levels of GluR1-1 flop mRNAs do not exhibit significant changes (Guan, Y. *et al.*, 2003). GluR1 serine 831 phosphoprotein levels are also increased as early as 30 min after inflammation. The increase in GluR1 phosphorylation depends on primary afferent input and interestingly, is blocked by NMDA receptor antagonists, suggesting an NMDA receptor-mediated modification of AMPA receptor function in the RVM circuitry.

These findings indicate that EAA receptors in the RVM undergo selective transcriptional, translational, and posttranslational modulation following inflammation. The activity-induced plasticity in descending circuitry complements the hyperexcitability in ascending pain transmission pathways (Dubner, R. and Ruda, M. A., 1992). The increased neuronal barrage at the spinal level activates spinal projection neurons that then activate glutamatergic, opioidergic, and presumably GABAergic neurons at the brainstem level leading to a similar but not necessarily identical form of neuronal plasticity.

5.49.3.2.5 Changes in sensitivity to opioids

5.49.3.2.5.(i) Increased analgesic potency Rats with inflammatory hyperalgesia exhibit an increased sensitivity to opioid analgesics (Neil, A. *et al.*, 1986). Typically, there is a leftward shift of the dose-response curve for opioids from the inflamed hyperalgesic paw when compared to the noninflamed paw (Hylden, J. L. K. *et al.*, 1991). Kayser V. *et al.* (1991) suggest that this increased opioid sensitivity in inflamed animals is related to a peripheral mechanism as it is significantly attenuated after local injections of very low doses (0.5–1 μg) of naloxone. Ossipov M. H. *et al.* (1995) demonstrate that the increased morphine analgesic potency is mediated through delta opioid receptors. This delta-mediated effect may require mu-opioid receptor-induced trafficking of delta-receptors to neuronal membranes (Morinville, A. *et al.*, 2003). The increased opioid sensitivity after inflammation may also be explained by changes in central pain modulating pathways. Hurley R. W. and Hammond D. L. (2000; 2001) demonstrate enhancement and plasticity of the descending inhibitory effects of mu and delta 2 opioid receptor agonists microinjected into the RVM during the development and maintenance of inflammatory hyperalgesia.

5.49.3.2.5.(ii) Opioid tolerance and hyperalgesia Hyperalgesia may occur after long exposure to opioids as opioid tolerance develops (Mao, J., 2002). The underlying mechanisms may involve activity of the pain modulatory circuitry. Morphine-tolerant rats exhibit an increased glutamate synaptic transmission in RVM neurons (Bie, B. and Pan, Z. Z., 2005). Chronic morphine treatment induces delta receptor-mediated synaptic inhibition in PAG neurons that is not seen in the untreated mice (Hack, S. P. *et al.*, 2005). The activation of descending pain facilitatory pathways from the RVM and an increase in CCK activity may contribute to hyperalgesia after prolonged morphine exposure (Ossipov, M. H. *et al.*, 2005).

5.49.3.2.6 Aging-related alteration in descending pain modulation

Iwata K. *et al.* (2002) have reported age-related plasticity in descending pathways in rats. It is found that, in aged rats, there is an increased dorsal horn nociceptive neuronal activity and nocifensive behavior associated with a significant loss of serotonergic and noradrenergic fibers in the spinal dorsal horn. These results suggest a reduced descending inhibition with advancing age. Human studies concur that the DNIC, a form of endogenous pain inhibition, is reduced in the older adults (Edwards, R. R. *et al.*, 2003).

5.49.3.3 Significance of Altered Descending Modulation in Persistent Pain

Descending pathways modulate the intensity of perceived pain under normal conditions and persistent pain as a result of injury. The activity-dependent plasticity within the pain modulatory circuitry is a normal function of the brain and presumably is activated to protect the organism from further environmental injury. The dynamic changes in descending modulation after inflammation and primary hyperalgesia and allodynia are protective. The early facilitation may function to enhance nocifensive escape behavior whereas the dominant late inhibition may provide a mechanism by which movement of the injured site is suppressed or reduced to aid in healing and recuperation. Gebhart G. F. (2004) proposes that the need to escape from a predator requires enhanced control of pain and thus more descending inhibition, which is supported by opioid and nonopioid mechanisms of stress-induced analgesia seen in animals (Hayes, R. L. *et al.*, 1978). However, the significance of the enhanced descending facilitation found at sites of secondary hyperalgesia and after nerve injury is unclear. Gebhart G. F. (2004) hypothesizes that descending facilitation is necessary to maintain hyperalgesia as the tissue heals and to protect the injured tissue from further insult. The enhanced descending pain modulation clearly includes shifts in the balance between inhibitory and facilitatory components. Present evidence suggests that there is a different balance in neural networks receiving input from zones of secondary hyperalgesia where there is

no primary injury. The balance toward facilitatory influences appears to be maintained for longer periods. Activation of these sites would lead to an enhancement of movement behavior that could also be protective.

Injury to neural tissues will also upset the balance between facilitation and inhibition. The dynamic plasticity of descending pathways after peripheral nerve injury leading to neuropathic pain may render the system vulnerable and lead to pathological consequences. In this situation, the initiation of hyperalgesia is not dependent upon descending facilitation, whereas the maintenance of the hyperalgesia for long periods of time is dependent on such descending facilitation. Nerve injury may activate a descending nociceptive system that normally is protective but can become a source of persistent pain after pathology in the nervous system.

5.49.4 Therapeutic Implications: Activating Descending Pathways

The mechanisms underlying various clinical approaches for analgesia and pain control involve activation of descending pathways. One important area of research is to find efficient and selective ways to activate endogenous descending pathways for pain control.

5.49.4.1 Electrical Stimulation

Electrical stimulation has been applied to the all levels of the nervous system to produce analgesia or pain attenuation. Presumably, this approach activates endogenous pain control including the descending pathways to the spinal cord. However, the underlying mechanisms for the stimulation-produced analgesia, particularly the selectivity of the stimulation against certain types of chronic pain in humans, remain to be elucidated.

5.49.4.1.1 Brain stimulation

Stimulation-produced analgesia has been confirmed in humans (Kumar, K. *et al.*, 1997; Wallace, B. A. *et al.*, 2004). For pain control, the most commonly used sites for deep brain stimulation have been the periventricular gray and PAG regions, which is consistent with findings in animal studies that these areas are involved in opioid analgesia and descending pain inhibition. Practically, this approach is only considered on patients suffering from intractable pain refractory to other treatments.

5.49.4.1.2 Spinal cord stimulation

Effective pain control can be achieved by direct spinal cord stimulation (SCS) through an implanted stimulator in the epidural space (Shealy, C. N. *et al.*, 1967; Janfaza, D. R. *et al.*, 1998). In theory, spinal stimulation can bypass brainstem circuitry to directly activate descending fibers or antidromically excite collaterals of ascending fibers that indirectly inhibit projection neurons, leading to inhibition of pain transmission at the spinal level. However, the mechanisms of SCS-produced pain relief are more complex (Meyerson, B. A. and Linderoth, B., 2000). One interesting aspect is that SCS is selectively effective against neuropathic pain and hyperalgesia, leaving normal nociceptive threshold unaffected (Meyerson, B. A. and Linderoth, B., 2000).

5.49.4.1.3 Vagal stimulation

Animal studies have provided evidence that stimulation of vagal afferent fibers produces antinociception, although low intensity may facilitate pain (Randich, A. and Gebhart, G. F., 1992). Taking advantage of the approved vagal stimulation approach for epilepsy, the effect of vagal stimulation on pain has been confirmed in humans (Kirchner, A. *et al.*, 2000; Ness, T. J. *et al.*, 2000). Vagal stimulation may offer another alternative method for activating the body's pain control system.

5.49.4.1.4 Transcutaneous electrical nerve stimulation

Peripheral stimulation can be applied through transcutaneous electrical nerve stimulation (TENS), an alternative modality for pain relief (Shealy, C. N., 2003). Although the results have been controversial, the clinical efficacy of this approach has been demonstrated by many studies. The effect of TENS is likely produced through modulation of the intrinsic spinal pain processing and release of endogenous opioids (Sluka, K. A. and Walsh, D., 2003).

5.49.4.2 Pharmacological Approaches

5.49.4.2.1 Opioids

Opioid agents have been used extensively for analgesia. Even applied peripherally, a central action involving activation of the endogenous pain control system is required for the analgesic effect of the opioids. The opioids are potent and efficacious

analgesics. However, their side effects have limited their use in chronic pain conditions.

5.49.4.2.2 Alpha 2 adrenoceptor agonists

Extensive documentation of the role of descending noradrenergic pathways in pain inhibition provides the bases for the use of α_2 adrenoceptor agonists for analgesic purpose. Epidural clonidine for cancer pain is the approved application (Kamibayashi, T. and Maze, M., 2000). The use of the α_2 agonist can reduce the dose of fentanyl because of their synergistic action. Intrathecal clonidine has been shown to improve the effect of SCS (Schechtmann, G. *et al.*, 2004).

5.49.4.3 Peripheral Stimulation

5.49.4.3.1 Diffuse noxious inhibitory controls

Heterotopic noxious stimulation produces analgesia in humans (Reinert, A. *et al.*, 2000), which can be understood by the DNIC hypothesis proposed by Le Bars and colleagues (Le Bars, D. *et al.*, 1979a; 1979b). DNIC provides a rationale for understanding counterirritation-produced hypoalgesia and help in the design of nonpharmacological approaches for pain relief (see Chapter Diffuse Noxious Inhibitory Controls (DNIC)). Additionally, non-noxious manipulations also provide pain relief (Simkin, P. P. and O′Hara, M., 2002), presumably through modulation of pain processing by interfering stimuli.

5.49.4.3.2 Acupuncture

Acupuncture and moxibustion have been used for pain relief for thousands of years. The analgesic effect of acupuncture is related to the recruitment of endogenous opioids (Han, J. S., 2004; Zhang, R. X. *et al.*, 2004) and pain modulatory circuitry (Ma, F. *et al.*, 2004). Since a typical needling during the acupuncture treatment does not induce pain in humans, the mechanisms of acupuncture analgesia are likely different from that of DNIC.

5.49.4.4 Psychological Factors

5.49.4.4.1 Stress

Analgesia can be produced by stress through both opioid and nonopioid mechanisms (Hayes, R. L. *et al.*, 1978; Watkins, L. R. and Mayer, D. J., 1982). Stress activates the PAG–RVM pathway, which apparently is a mechanism of stress-induced antinociception (Bellchambers, C. E. *et al.*, 1998). Fear conditioning induces antinociception involving the amygdala, PAG, and RVM (Helmstetter, F. J. and Tershner, S. A., 1994). The relative painless state in the injured athlete or the wounded soldiers may be explained by stress-induced pain control related to a particular setting.

5.49.4.4.2 Placebo

Placebo analgesia may be mediated by endogenous opioids (Levine, J. D. *et al.*, 1978; Benedetti, F. and Amanzio, M., 1997). The imaging studies show that the neural substrate related to placebo effect on pain lies in the prefrontal and dorsal anterior cingulate cortex (Lieberman, M. D. *et al.*, 2004). It appears that expectation is a factor for triggering the placebo response (see Chapter The Placebo Effect) (Benedetti, F. *et al.*, 2003).

5.49.5 Concluding Remarks

Tremendous progress has been made in the past four decades on descending pain control mechanisms. In addition to well-established descending pain inhibition, the demonstration of descending pain facilitation provides a more complete picture of the body's endogenous pain modulatory system. The simultaneous descending excitatory and inhibitory inputs contribute to a balance between perception and suppression of noxious events. We now appreciate that the pain modulatory system undergoes dramatic changes after injury. There is a concurrent activation of brainstem descending inhibitory and facilitatory pathways and the interaction between these pathways will dictate, or affect, the development of neuronal hyperexcitability and behavioral hyperalgesia. The dynamic plasticity of descending pathways may sometimes render the system vulnerable and lead to pathological consequences. The imbalance between these modulatory pathways may be one mechanism underlying variability in acute and chronic pain conditions. For patients suffering from deep pains such as temporomandibular disorders, fibromyalgia, and low back pain, the diffuse nature and amplification of persistent pain, in part, may be the result of a net increase in endogenous facilitation.
